(Received 6 January 2014; published 16 April 2014)

An exact analytical solution is derived for the wave function of an electron in a one-dimensional moving quantum dot in a nanowire, in the presence of time-dependent spin-orbit coupling. For cyclic evolutions we show that the spin of the electron is rotated by an angle proportional to the area of a closed loop in the parameter space of the time-dependent quantum dot position and the amplitude of a fictitious classical oscillator driven by time-dependent spin-orbit coupling. By appropriate choice of parameters, we show that the spin may be rotated by an arbitrary angle on the Bloch sphere. Exact expressions for dynamical and geometrical phases are also derived.

Introduction and motivation.—The importance of a geometric phase factor in the adiabatic cyclic evolution of a nondegenerate quantum system was first discussed by Berry [1] and later extended to adiabatic cyclic evolution of a degenerate quantum system, for which the acquired geometric phase is non-Abelian [2]. Generalization to nonadiabatic cyclic evolutions was subsequently given for both nondegenerate [3] and degenerate quantum systems [4].

Since the original proposal of using the spin of an electron confined in a quantum dot (QD) as a qubit [5], a great deal of experimental and theoretical progress has been made on the road to realizing a quantum computer utilizing spins in QDs [6].

A successful way to achieve single spin manipulation is by employing electric-dipole induced spin resonance (EDSR) [7–14] using time-dependent electric fields, applied via gate electrodes. EDSR mediated by the spin-orbit interaction (SOI) [9] enables single spin manipulation as demonstrated in lateral QDs [15] and in QDs formed in nanowires [16–18]. Spin-flip times in such schemes are about 100 ns in lateral QDs [15] and below 10 ns in InAs nanowires [16]. Other theoretical proposals to exploit the SOI for single spin manipulations can be found in the literature [19–23].

Because of the spin-orbit interaction present in semiconductors [24,25], the single-electron orbital states in a QD are spin dependent and in the absence of a magnetic field the eigenstates are Kramers doublets, due to time-reversal invariance. A (spin-orbital) qubit can then be defined as the ground state Kramers doublet.

If the QD is displaced, the SOI induces rotations of the spin-orbital qubit [19]. Such rotations have been studied numerically [26] and analytically in the adiabatic limit [27–29]. By adiabatically moving the dot in closed loops (holonomies) general single-qubit manipulations can be achieved [27,28] which, together with the use of the Heisenberg exchange interaction for two-qubit manipulations, enables holonomic quantum computation [30,31] with spins in QDs [28]. Experimental progress to realize this idea has been reported recently in quadruple QD systems [32].

In this Letter we propose the manipulation of a spin-orbital qubit in a QD via motion in only one (physical) dimension, e.g., along a quantum wire, using time-dependent spin-orbit (Rashba) coupling with coupling parameter $\alpha(t)$, achieved electrically by changing the potential on a gate electrode [33]. This contrasts with previous proposals in which the parameter space is a two-dimensional position space [19,26–29]. Recently a sixfold tuning of $\alpha$ was demonstrated within 1 V of gate bias in an InAs nanowire [34].

To demonstrate single qubit manipulation, we give an exact analytical solution for the wave function of an electron in a one-dimensional moving quantum dot, modeled by a time-dependent harmonic confining potential in the presence of time-dependent spin-orbit coupling. This solution is itself interesting and adds to a limited number of exactly solvable time-dependent problems among which are general time-dependent harmonic oscillators [35,36], tunnel-coupled spin qubits driven by ac fields [37], and time-dependent two-level systems [38,39].

Model and exact solution.—We consider the Hamiltonian of a single electron in a one-dimensional system

$$H(t) = \frac{p^2}{2m^*} + \frac{m^*\omega^2}{2}[x - \xi(t)]^2 + \alpha(t)p\mathbf{n} \cdot \mathbf{\sigma}.$$  (1)

where $m^*$ is the electron effective mass and $\omega$ is the frequency of a harmonic trap (moving QD). The momentum and position operators are $p$ and $x$, respectively. The dot is translated with time-dependent position defined by the harmonic potential minimum at $\xi(t)$. The spin rotation axis due to the SOI $\alpha(t)$ is denoted by a unit vector $\mathbf{n}$, which
depends on the crystal structure of the quasi-one-dimensional material used and the direction of the applied electric field [18]. Pauli matrices and the identity in spin space are $\sigma$ and $I$, respectively.

Before presenting the solution, we give a simple example of the manipulation we have in mind. Consider a spin-orbital qubit in a nanowire QD with a constant Rashba SOI, $\alpha = \alpha_1$ and translation of the QD by some distance $\xi_0$. For adiabatic driving, this movement induces a rotation of the qubit on the Bloch sphere, which is proportional to the product $\xi_0\alpha_1$ [19]. For example, a spin flip can be realized if the distance traveled is $\pi/(2m^*\alpha_1)$. This can also be achieved by nonadiabatic movement of the QD, enabling spin flips with frequency of the order of the QD level achieved by nonadiabatic movement of the QD, enabling without SOI. The unitary transformation is a combination of spin flips with another action integral phase factor $\phi_{\alpha}$.

Starting position, while keeping $\alpha_2$ fixed and finally driving $\alpha$ back to its initial value $\alpha_1$, a unitary transformation is applied to the original manifold. This transformation depends only on the area of the loop in the parameter space of both drivings.

The exact solution of the time-dependent Schrödinger equation for $H(t)$ is obtained via a unitary transformation $U(t)$, chosen so that $H_0=U(t)H(t)U(t)^\dagger=U(t)H(t)U(t)^\dagger=H_0$, i.e., an oscillator at the origin without SOI. The unitary transformation is a combination of two transformations

$$ U(t) = \mathcal{A}_\alpha X_\xi, \quad (2) $$

where $X_\xi$ is the transformation into a frame moving with the QD [41]

$$ X_\xi = e^{-i\phi_\xi(t)}e^{im^*|x-x_c(t)|^2/2}e^{-i\phi(t)\tau}, \quad (3) $$

where the phase factor $\phi_\xi(t) = -\int_0^t L_\xi(\tau)d\tau$ is the action integral, with $L_\xi(t) = m^*\dot{x}_c(t)^2/2 - m^*\alpha^2[x_c(t) - \xi(t)]^2/2$ the Lagrange function of a driven oscillator and $x_c(t)$ is the response to the driving $\xi(t)$, i.e., the solution to the equation of motion of a classical driven oscillator

$$ \ddot{x}_c(t) + \alpha^2 x_c(t) = \omega^2 \xi(t). \quad (4) $$

For constant $\alpha$ the transformation is given by $A_\alpha = e^{-im^*x_0\alpha}\sigma$ as shown in Refs. [40,42]. For time-dependent $\alpha(t)$ this must be generalized to

$$ A_\alpha = e^{-i(\phi_\alpha(t) + m^*\dot{x}_c(t)\alpha(t)/\omega^2 + \phi(t)\tau)n \cdot \sigma)} \times e^{-i\phi_\alpha(t)mn_{\alpha}/\alpha^2 e^{-im^*x_0(t)n \cdot \sigma}}, \quad (5) $$

with another action integral phase factor $\phi_\alpha(t) = -\int_0^t L_\alpha(\tau)d\tau$, where $L_\alpha(t) = m^*\dot{x}_c(t)^2/(2\alpha^2) - m^*\alpha^2\dot{x}_c(t)^2/2 + m^*\alpha(t)\alpha(t)$ is the Lagrange function of another driven oscillator, satisfying

$$ \ddot{a}_c(t) + \alpha^2 a_c(t) = \alpha^2 \alpha(t) \quad (6) $$

and a phase factor $\phi(t) = -m^*\int_0^t \dot{a}_c(\tau)\dot{x}_c(\tau)d\tau$. By analogy with the transformation $X_\xi$, we may regard this generalized $A_\alpha$ as transforming into the “moving frame” of the spin-orbit coupling, while also performing a momentum-dependent spin rotation. The phase $\phi(t)$ is a crucial term that rotates the spin and we will focus on it later. Note also the equivalence of classical equations of motion for driven oscillators Eqs. (4) and (6); thus, the analysis of the classical driving of position [40] can also be applied to the driving of the SOI.

The solution of the original Hamiltonian Eq. (1), $|\Psi(t)\rangle$, is obtained directly via the unitary transformation Eq. (2), i.e., $|\Psi(t)\rangle = U(t)|\Psi(0)\rangle$, where $|\Psi(0)\rangle$ is a solution of the transformed Hamiltonian $H_0$. Thus we have

$$ |\Psi(t)\rangle = U(t)|\Psi(0)\rangle, \quad (7) $$

where $U(t) = U(t)e^{-iH_0T}|\Psi(0)\rangle$ is the time evolution operator. For the cases when the initial state is an eigenfunction of $H_0$, i.e., $|\Psi_{m_0}(0)\rangle = U(t)|\psi_{m_0}\rangle|\chi_s\rangle$, where $|\psi_{m_0}\rangle$ is the $m_0$th eigenfunction of the undriven harmonic oscillator $H_0$ and $|\chi_s\rangle$ is a spinor with spin $s$, the time evolved state simplifies to

$$ |\Psi_{m_0}(t)\rangle = e^{-i\omega_{m_0}T}|U(t)|\psi_{m_0}\rangle|\chi_s\rangle, \quad (8) $$

where $\omega_{m_0} = (m + (1/2))\omega$.

Henceforth we shall consider only systems with cyclic evolutions, i.e., cases where the Hamiltonian equation (1) after time $T$ returns to its initial form, $H(T) = H(0)$ with the state spanning the same Kramers doublet subspace defined by $m$, allowing arbitrary superpositions of the two Kramers’ states. To ensure periodic behavior the driving parameters $\xi(t)$ and $\alpha(t)$ are chosen so that $\xi(t + T) = \xi(t)$, $\alpha(t + T) = \alpha(t)$ and via the classical oscillator equations of motion Eqs. (4) and (6), also $x_c(t + T) = x_c(t)$ and $a_c(t + T) = a_c(t)$. This can be achieved using specific drivings in both adiabatic and nonadiabatic regimes [40]. The final state after cyclic evolution is given by Eq. (8) for which, at $t = T$, the time evolution operator reduces to the simple non-Abelian $U_2(2)$ transformation, $U(T) = e^{i\Phi_T}$,

$$ \Phi_T = \left[ -\omega_mT + \int_0^T L(\tau)d\tau \right] I - \phi_T n \cdot \sigma, \quad (9) $$

where $L(\tau) = L_\xi(\tau) + L_\alpha(\tau)$ is the Lagrange function of a classical two-dimensional oscillator, and the angle of spin rotation around $n$, $2\phi_T = 2\phi(T)$, is given by

$$ \phi_T = m^* \int_{C_1} a_c(\xi)d\xi = m^* \int_{C_1} a_c(\xi)d\xi, \quad (10) $$

where $a_c(\xi)$ is the response $a_c(t)$ expressed as a function of the driving $\xi(t)$ and the contour $C_1$ is the path in the
parametric space \([\xi(t), a_c(t)]\). Similarly, \(a[x_c] \) is the driving \(a(t)\) expressed as a function of the response \(x_c(t)\) and \(C_{ad}\) is the path in the parametric space \([x_c(t), a(t)]\).

In the adiabatic limit, \(x_c(t) \to \xi(t)\) and \(a_c(t) \to a(t)\). The total phase, Eq. (9) may then be decomposed into dynamical and geometric Wilczek-Zee parts \([2]\), \(\Phi_T = \Phi_{dyn} + \Phi_{geom}\), with

\[
\Phi_{dyn} = -\left[\alpha m T - \frac{1}{2} m^* \int_0^T \alpha^2(t) \, dt\right] I, \tag{11}
\]

\[
\Phi_{geom} = -\phi_{ad} n \cdot \sigma, \quad \phi_{ad} = m^* \int_{C_{ad}} \alpha[\xi] d\xi. \tag{12}
\]

Note that \(\phi_{ad}\) is expressed solely in terms of the driving functions and the contour \(C_{ad}\) corresponds to the path in the parametric space \([\xi(t), a(t)]\), similar to the case of Berry phase for a nondegenerate state \([1]\).

**Examples of holonomic spin manipulations.**—The exact expression for the angle of spin rotation, Eq. (10), is the central result of this paper from which pseudospin transformations within the Kramers doublet may be implemented via nonadiabatic evolution. The phase is proportional to the area in the parametric space of the displacement driving and the spin-orbit response (or equivalently the spin-orbit driving and displacement response). Although the periodic driving functions are arbitrary, a particularly convenient driving scheme is to change \(\xi(t)\) and \(a(t)\) sequentially, returning to the displaced Kramers doublet space at intermediate times, between which the evolution may be manifestly nonadiabatic with spin rotations. This is illustrated in Figs. 1(a) and 1(b) in which at times \(t_1\), \(t_2\), \(t_3\), and \(t_4\) the response functions are equal to the driving functions, with zero time derivatives, ensuring that at these times we return to the displaced Kramers doublet space.

From these time variations of driving terms and responses we see that the parametric plot of \([\xi(t), a_c(t)]\) is a square (in scaled units), as shown in Fig. 1(c). Comparing drivings and responses, we see that although we are in the nonadiabatic regime, from Eq. (10) the acquired non-Abelian phase is calculated to be \(\phi_T = -m^* \xi_0 a_0\), the adiabatic result. It follows that \(\phi_T\) is independent of the specific choice of drivings, provided there are no residual oscillations at the vertices. The only difference between the various cases is the cycle time \(T\), which is a minimum for the highly nonadiabatic case of instantaneous switching [thin dashed lines in Figs. 1(a) and 1(b)] \([40]\), with similar behavior for \(a(t)\). Explicit calculation gives \(T = 4\pi/\omega\). An estimate for InSb gives \(\phi_T \sim 1\), using parameters \(m^* = 0.015 m_e\), \(\xi_0 = 200\) nm, and \(a_0 = 50\) nm/ps \([18]\). Within the expected range of allowed parameters, we see that arbitrary rotations about a fixed axis \(n\) are feasible. This rotation axis itself may be changed using additional side gates, thus opening the possibility of arbitrary rotation on the Bloch sphere.

The independence of acquired phase to the switching profile of \(\xi(t)\) and \(a(t)\), and its equivalence to the adiabatic result, is a consequence of sequentially switching these driving terms and is not generally true. An example is shown in Fig. 1(d) for which \(\xi(t) = \xi_0 \cos(\omega t/n)\) and \(a(t) = a_0 \sin(\omega t/n)\), with integer \(n \geq 2\). In the adiabatic limit \((n \to \infty)\), the parametric plot is a circle when spin-orbit and displacement parameters are scaled with \(a_0\) and \(\xi_0\). However, unlike the previous example, the trajectories and the acquired phase deviate from the adiabatic limit, as can be seen by the red contour line \(C_1\) corresponding to \(n = 4\) \([43]\).

**Relation to geometric phases.**—Anandan has extended the definitions of dynamical and geometric phases to cases of nonadiabatic cyclic evolution of degenerate systems \([4]\). Using our exact solution, we may derive explicit expressions for these contributions to the total phase.

We focus on cases where at \(t = 0\) our system is in a degenerate Kramers doublet state, Eq. (8). This state undergoes cyclic evolution in time \(T\) where it is again in the same Kramers doublet space but with a non-Abelian spin transformation with total phase given by Eq. (9). Note, however, that, due to nonadiabatic evolution, the state at
intermediate times will generally be a superposition of other Kramers doublets when expressed in the instantan-
eous eigenbasis set at time $t$.

To divide the phase into dynamical and geometric parts we first choose a gauge transformation to another

\[
\Phi(t) = \int_0^t L(\tau) d\tau - \phi(\tau) \mathbf{n} \cdot \mathbf{A}.
\]

spanning the same subspace but with periodic basis states,$\left|\Psi_{ms}(T)\right\rangle = \left|\Psi_{ms}(0)\right\rangle$, since $\Phi(T) = \Phi_T$, $\Phi(0) = 0$. The
time evolution operator, Eq. (7), after one cycle can then be expressed as [4]

\[
U(T) = e^{i\Phi_T} = T e^{\int_0^T \left[A(\tau) - K(\tau)\right] d\tau},
\]

where $T$ denotes the time ordering operator. Hermitian

\[
A_{st'} = i\left<\Psi_{ms}(\tau)|d/d\tau|\Psi_{ms'}(\tau)\right>,
\]

\[
K_{st'} = \left<\Psi_{ms}(\tau)|H(\tau)|\Psi_{ms'}(\tau)\right>,
\]

matrices $A_{st'} = i\left<\Psi_{ms}(\tau)|d/d\tau|\Psi_{ms'}(\tau)\right>$ and $K_{st'} = \langle\Psi_{ms}(\tau)|H(\tau)|\Psi_{ms'}(\tau)\rangle$ can be, by the virtue of exact

functions Eq. (8), expressed analytically in terms of driving

\[
\phi_{Dyn} = -\int_0^T K(\tau) d\tau
\]

and response functions. The resulting $A$ and $K$ commute

\[
\phi_{geom} = \int_0^T A(\tau) d\tau,
\]

allowing the total phase to be split into $\Phi_T = \Phi_{Dyn} + \Phi_{Geom}$, where

\[
\Phi_{Dyn} = -\int_0^T E(\tau) d\tau - 2(\phi_T - \phi_c) \mathbf{n} \cdot \mathbf{A},
\]

\[
\Phi_{Geom} = \phi_n I + (\phi_T - 2\phi_c) \mathbf{n} \cdot \mathbf{A},
\]

and $E - \omega_m = m^* (\hat{x}^2 + \hat{a}^2/\omega^2) + m^* \alpha \omega^2 (x_c - \xi)^2/2 + m^* \alpha_c/2 - m^* \alpha \alpha_c$ is instantaneous energy of driven
classical oscillators, and

\[
\phi_c = m^* \int_{C_{0}} a_c |x_c| d\xi,
\]

\[
\phi_n = m^* \left( \int_{C_{0}} \hat{x}_c |x_c| d\xi + \int_{C_{0}} \hat{a}_c |a_c| d\omega^2 / \omega^2 \right).
\]

Finally, let us relate our results corresponding to the
cyclic evolution of a degenerate system to results valid for
nondegenerate systems. Degeneracy of the Kramers states

\[
Q_r(\phi) = g_{r\beta} \phi_{\beta} - g_{r\alpha} \phi_{\alpha}.
\]

Eq. (8) can be lifted, e.g., by an external magnetic field

\[
H(t) + H_z = -g \mu_B B \cdot \mathbf{n}.
\]

which breaks the time reversal symmetry. We consider

\[
\chi_i = \left|\chi_i\right\rangle\langle\chi_i\rangle,
\]

the case with the magnetic field along the direction of the
effective field induced by the moving QD due to SOI, i.e.,

\[
H(t) + H_z = -g \mu_B \hat{B} \cdot \mathbf{n}.
\]

with the Zeeman term $H_z = -g \mu_B B \cdot \mathbf{n}$. For more general
cases the exact solution may still give new insight by

\[
\phi_{\beta} \rightarrow \theta_{\beta / 2}
\]

treating the magnetic field component perpendicular to $\mathbf{n}$ as a perturbation. The solutions to a driven

\[
H(t) + H_z
\]

Hamiltonian $H(t) + H_z$ are in this case also given by Eq. (8), but

\[
\phi_{\beta} \rightarrow \theta_{\beta / 2}
\]

with states $|\chi_i\rangle$ being spinor eigenstates in a magnetic

\[
\phi_{\beta} \rightarrow \theta_{\beta / 2}
\]

field, with eigenenergy $\omega_m = (m + 1/2)\omega + g \mu_B B_s$ for

\[
\phi_{\beta} \rightarrow \theta_{\beta / 2}
\]

$s = \pm (1/2)$, respectively. In this case the Aharonov-

\[
\phi_{\beta} \rightarrow \theta_{\beta / 2}
\]

Anandan geometric phase [3] can also be expressed exactly,

\[
\beta_s = \int_0^T \left<\Psi_{ms}|d/d\tau|\Psi_{ms}\right>d\tau = \phi_s \pm (\phi_T - 2\phi_c),
\]

in the adiabatic limit reduces to the ordinary

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

Berry phase $\beta_s \rightarrow \theta_{\beta / 2}$.

**Discussion and conclusion.**—Geometric phase has

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

recently been measured in a driven harmonic oscillator,

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

implemented as one of the electromagnetic modes of a

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

transmission line resonator using a superconducting qubit as

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

a nonlinear probe of the phase [45]. With respect to this

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

experiment the driven harmonic oscillator considered here,

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

Eq. (1), has an additional internal degree of freedom (spin)

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

which the driving of the momentum couples to. This suggests

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

the possibility of including an additional degree of freedom

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

also in experiment, e.g., the polarization of a photon, together

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

with its coupling, to observe the non-Abelian phases.

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

Compared with other proposals, such as EDSR or inverse

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

engineering [23], in our scheme the spin control is all electrical

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

without magnetic field; thus, qubit errors from fringing

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

magnetic fields are no longer an issue. Furthermore, our

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

general exact solution allows extensive exploration and

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

optimization of the model, including the nonadiabatic regime,

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

in contrast to EDSR where SOI [7,9] or Zeeman terms [13] are

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

treated as perturbations, restricting applicability.

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

Possible effects of the environment on the pseudospin

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

state of an electron in a moving QD are decoherence and

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

relaxation due to fluctuating electric fields, caused by the

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

piezoelectric phonons and conduction electrons in the

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

circuit [27,46], due to hyperfine interaction with the nuclei

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

[47] or ionized dopant nuclei in a heterostructure [48]. In

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

the last case the longitudinal and transverse rates are at the

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

lowest order in SOI proportional to the speed of the moving

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

QD [see Eq. (28) in Ref. [48]] which applies in our case for

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

linear ramp driving in the adiabatic limit [40]. The spin

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

relaxation of free and QD-localized electrons with spin-

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

orbit coupling disorder has also been studied [49] though

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

not in the moving QDs. An important consideration in the

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

practical implementation of this scheme is the affect of

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

random fluctuations in both the time-dependent SOI and the

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

QD motion. Although a detailed investigation of this is

\[
\beta_s \rightarrow \theta_{\beta / 2}
\]

beyond the scope of the present Letter, we point out that our
method and exact solution applies to arbitrary drivings of both the QD motion and time-dependent SOI and could therefore be used as a starting point for a detailed study of noise properties, which would be welcome. This would extend the already promising results for static disorder of adiabatic QD motion [48] and spin-orbit coupling disorder [49].

To conclude, we have presented a formalism for the analysis of holonomic spin–orbit qubit manipulations, where the non-Abelian $U(2)$ phase acquired during one cycle is exactly given by the contour integral in the space of time-dependent QD position and Rashba interaction response. The time evolution operator $U(t)$ and hence also the wave function, is completely determined by the driving parameters $\xi, \alpha$ and their responses $x_\alpha, a_\alpha$. Analytical expressions derived allow a detailed analysis of different types of driving, with potential application to the design and optimization of high-speed qubit gates. Explicit expressions for dynamic and geometric phases enable the off-diagonal (spin-rotation) part to be arbitrary, shared between them.

Here we give two examples of periodic motion for which the drivings $\xi(t)$ and $\alpha(t)$ vary simultaneously and for which the state returns to the initial Kramers subspace after a complete period, $T$. The first example (circular driving) demonstrates the transition from highly non-adiabatic to adiabatic driving and shows clearly the effect of non-adiabatic motion on the various parametric contours. These are also seen in the second example (broken ellipsoidal driving) which can give rather exotic trajectories and for which we also show how an arbitrary division between dynamic and geometric phases can be made. This contrasts with the scenario discussed in the text for which $\xi(t)$ and $\alpha(t)$ are varied sequentially returning to the displaced Kramers subspace at intermediate times, which always gives square contours for the parametric plots, the adiabatic result.

DRIVING AND RESPONSE

The exact time evolution operator $U(t)$ is completely determined, firstly by the quantum dot time-dependent displacement coordinate $\xi(t)$ and time-dependent Rashba coupling $\alpha(t)$ and secondly by the response to these two driving functions. Displacement response $x_c(t)$ and spin-orbit response $a_c(t)$ are related to drivings by an uncoupled set of harmonic equations of motion,

$$\ddot{x}_c(t) + \omega^2 x_c(t) = \omega^2 \xi(t),$$

$$\ddot{a}_c(t) + \omega^2 a_c(t) = \omega^2 \alpha(t).$$

In the present case we seek periodic response to periodic driving. Of a particular interest are the solutions where the initial (and final) values of driving and response coincide. For example, when $x_c(0) = 0$ and $\dot{x}_c(0) = 0$, the solution is given by

$$x_c(t) = \omega \int_0^t \sin[\omega(t - \tau)]\xi(\tau)d\tau,$$

and in order to fulfill the condition of periodicity of the response, the driving has to be appropriately tuned. Since the equations of motion correspond to undamped oscillators, in general only discrete values of one cycle period $T$ are possible. Equations of motion can efficiently be solved by Fourier expansion in the time domain and then analytical solution is possible for a broad class of drivings.

CIRCULAR DRIVING

![Fig. S1: Position $\xi(t)/\xi_0$ and the SOI $\alpha(t)/\alpha_0$ (full) as functions of driving time $t/T$ and responses $x_c(t)/\xi_0$, $a_c(t)/\alpha_0$ (dashed). Panel (a) shows fast, non-adiabatic driving, $n = 3$, i.e., $T = 3T_0$, and panel (b) a slower driving with $n = 8$. Fast oscillations correspond to frequency of the oscillator, $\omega = 2\pi/T_0$.]

Here we consider driving corresponding to a circular path $\alpha[\xi]$ with constant frequency, $\xi(t) = \xi_0 \cos(\omega t/n)$ and $\alpha(t) = \alpha_0 \sin(\omega t/n)$, where $n \geq 2$ is integer, the period is $T = nT_0$ and $T_0 = 2\pi/\omega$. Periodic responses with $x_c(0) = \xi(0)$ and $a_c(0) = \alpha(0)$ are given by

$$x_c(t) = \frac{\xi_0}{n^2} \cos(\omega t/n) - \cos(\omega t),$$

$$a_c(t) = \frac{\alpha_0 n}{n^2 - 1} (n \sin(\omega t/n) - \sin(\omega t)).$$
The phases (see Eq. (10), (17) and (18)) are given analytically,

\[\phi_{ad} = m^* \oint_{C_{ad}} \alpha[x_c]d\xi = -\pi m^* \xi_0 \alpha_0,\]
\[\phi_T = m^* \oint_{C_1} \alpha[x_c]d\xi = m^* \oint_{C_2} \alpha[x_c]dx_c = \frac{n^2}{n^2 - 1} \phi_{ad},\]
\[\phi_c = m^* \oint_{C_3} a_c[x_c]dx_c = \frac{n^2(n^2 + 1)}{(n^2 - 1)^2} \phi_{ad},\]
\[\phi_\alpha = m^* (\oint_{C_4} \dot{x}_c[x_c]dx_c + \oint_{C_5} \dot{a}_c[a_c](dx_c/\omega^2)) = \frac{\pi m}{n} \frac{(n^2 + 1) \xi_0^2 \omega + 2n^3 \alpha_0^3/\omega}{(n^2 - 1)^2}.\]

\(\phi_T\) is in fact independent of the initial values \(x_c(0), a_c(0), \dot{x}_c(0),\) and \(\dot{a}_c(0)\) in spite of the fact that the contours \(C_{1,2}\) strongly depend on the choice of the initial values. Note also that \(\phi_c/\phi_T > \phi_T/\phi_{ad} > 1\) and \(\phi_\alpha > 0\) while in the adiabatic limit, \(n \to \infty, \phi_T = \phi_c = \phi_{ad}\) and \(\phi_\alpha = 0.\)

In Fig. S1(a) is presented normalized displacement \(\xi(t)/\xi_0\) and the SOI \(\alpha(t)/\alpha_0\) as functions of driving time \(t/T\) for \(n = 3\) (full lines). Dashed lines correspond to the response functions \(x_c(t)/\xi_0\) and \(a_c(t)/\alpha_0.\) The spin-orbit response exhibits a more pronounced oscillatory behavior, because the initial condition, at \(t = 0,\) was chosen \(\dot{a}_c(0) = 0,\) which differs from \(\dot{\alpha}(0) > 0.\) For the displacement we chose \(\dot{\xi}_c(0) = \xi(0)\) which leads to a more synchronized motion. In Fig. S1(b) analogous results for \(n = 8\) are presented and here also \(a_c(t)\) displays a higher degree of oscillations which would by progressively larger \(n\) diminish as \(O(1/n).\)

Examples of trajectories \([\xi(t), a_c(t)]\) (contours \(C_1\)) are shown in Fig. S2(a) from the fastest non-adiabatic \(n = 2\) case towards adiabatic with \(n = 16\) and the adiabatic limit \(n \to \infty\) result corresponds to the driving \([\xi(t), \alpha(t)].\) Bullet represents the initial point at \(t = 0.\) In Fig. S2(b) the corresponding results for \([\alpha(t), x_c(t)]\) represent contours \(C_2.\) Although the shapes of \(C_1\) and \(C_2\) are different, the enclosed area for the same \(n\) is equal. Note that \(C_2\) exhibits much less oscillations, consistent with Fig. S1. The last of three important trajectories, \([x_c(t), a_c(t)],\) contour \(C_3,\) is presented in Fig. S2(c).

The last set of contours corresponds to the paths in the phase space of separate, displacement and spin-orbit degrees of freedom. In Fig. S3(a) is shown \([x_c(t), \dot{x}_c(t)],\) the contour \(C_1.\) In the adiabatic limit it shrinks to the line leading to vanishing enclosed area. The corresponding \([a_c(t), \dot{a}_c(t)]\) trajectory, the contour \(C_5,\) is presented in Fig. S3(b), in the adiabatic limit a line decorated by superimposed oscillations.

---

Fig. S2: Panel (a): Contours \([\xi(t), a_c(t)]\) or \(C_1\) (scaled) for various \(n = 2, 4, 16\) and the adiabatic limit \(n \to \infty\) (circular contour \(C_{ad}\)). Panel (b): Contours \([x_c(t), \alpha(t)]\) corresponding to \(C_2;\) colors for \(n = 2, 4, 16, \infty\) as in panel (a). Note entirely different \(C_1\) and \(C_2,\) but still \(\oint_{C_1} a_c[\xi]d\xi = \oint_{C_2} a_c[x_c]dx_c\) for each \(n.\) Panel (c): Contours \([x_c(t), a_c(t)]\) or \(C_3.\) In all panels bullets represent start (end) of a cycle, with \(x_c(0) = \xi_0,\) \(\dot{x}_c(0) = 0\) and \(a_c(0) = 0, \dot{a}_c(0) = 0.\) Note also that in the adiabatic limit all contours reduce to circle \(C_{ad}.\)
one cycle are given by

\[ x_c(t) = \frac{2}{3} \xi_0 \left[ 2 \sin \left( \omega t/2 \right) - \sin(\omega t) \right] \Theta(t) \Theta(2T_0 - t), \]
\[ a_c(t) = \alpha_0 x_c(t - \Delta T)/\xi_0. \]

Phases \( \phi_T, \phi_c, \) and \( \phi_{ad} \), calculated as a function of delay \( \Delta T/T_0 \), are presented in Fig. S5(a). There are several interesting details to be noted: (i) all curves are similar in the sense that particular phase for small \( \Delta T \) is negative and by progressively larger time delay at some point changes sign and finally vanishes at \( \Delta T = 2T_0 \), where there is no overlap between \( \xi(t) \) and \( a_c(t) \), see Fig. S4. (ii) All phases mutually intersect in two \( \Delta T \) points, therefore \( \phi_T \) can be tuned to be equal to \( \phi_c \), which eliminates off-diagonal parts of the dynamical phase, for example. It is evident also that one can tune \( \phi_T = 2\phi_c \) which eliminates off-diagonal parts of the geometric phase [see also Fig. S5(b)]. (iii) Due to the fact that each of the phases at some point vanishes and changes sign, the ratio between any pair of phases can take any value, positive or negative. Since the amplitudes of drivings, \( \xi_0 \) and \( \alpha_0 \), are additional free parameters, consequently one can by changing \( \Delta T \) tune the phases to any value – independently.

Here we consider driving corresponding to the path \( \alpha[\xi] \) with \( \xi(t) = \xi_0 \sin \left( \omega t/2 \right) \Theta(t) \Theta(2T_0 - t) \), and \( \alpha(t) = \alpha_0 \xi(t - \Delta T)/\xi_0 \), where \( \Theta(t) \) is the Heaviside step function, \( T_0 = 2\pi/\omega \) and \( \Delta T \) is the time delay (see Fig. S4). The driving is applied periodically with the cycle period \( T = 2T_0 + \Delta T \). The responses are periodic and within

Fig. S4: Position \( \xi(t)/\xi_0 \) and the SOI \( \alpha(t)/\alpha_0 \) as functions of driving time \( t/T \) and the corresponding responses \( x_c(t)/\xi_0, a_c(t)/\alpha_0 \). Note that the time-dependence of SOI is delayed by \( \Delta T \), otherwise with time-dependence identical to the displacement driving.

Fig. S3: Panel (a) shows scaled phase space contours \([x_c(t), \dot{x}_c(t)]\) or \( C_4 \) and panel (b) \([a_c(t), \dot{a}_c(t)]\) or \( C_5 \), for various \( n = 2, 4, 16 \). In the adiabatic limit, \( n \to \infty \), \( \dot{x}_c(t) = \dot{a}_c(t) = 0 \).

BROKEN ELLIPSOIDAL DRIVING
Contours \([\xi(t)/\xi_0, a_c(t)/a_0], [x_c(t)/\xi_0, a_c(t)/a_0]\) and \([\xi(t)/\xi_0, \alpha(t)/\alpha_0]\) are presented in Fig. S6. In panels (c) and (d) note the reversion of the directions of \(C_{1,3,\text{ad}}\) which is the reason for the change of sign of the phases shown in Fig. S5. In all panels bullets represent start (end) of a cycle, with \(x_c(0) = x_c(T) = 0, \dot{x}_c(0) = \dot{x}_c(T) = 0, a_c(0) = a_c(T) = 0, \) and \(\dot{a}_c(0) = \dot{a}_c(T) = 0.\)

Scaled phase space contours \([x_c(t), \dot{x}_c(t)]\) and \([a_c(t), \dot{a}_c(t)]\) are identical to the case of circular motion for SOI response \([a_c(t), \dot{a}_c(t)],\) Fig. S3(b) for \(n = 2,\) with the displacement response appropriately scaled by \(\xi_0/a_0.\)

Fig. S6: Contours \([\xi(t)/\xi_0, a_c(t)/a_0] (C_1), [x_c(t)/\xi_0, a_c(t)/a_0] (C_3)\) and \([\xi(t)/\xi_0, \alpha(t)/\alpha_0] (C_{\text{ad}}).\) Panels (a), (b), (c), (d) correspond to different values of \(\Delta T/T_0 = 1/4, 5/8, 3/4, 5/4,\) respectively (in Fig. S5(a) indicated by dashed lines).
