A self-consistent theory is proposed for the general problem of interacting undulating fluid membranes subject to the constraint that they do not interpenetrate. We implement the steric constraint via an exact functional integral representation and, through the use of a saddle-point approximation, transform it into a novel effective steric potential. The steric potential is found to consist of two contributions: one generated by zero-mode fluctuations of the membranes and the other by thermal bending fluctuations. For membranes of cross-sectional area \( S \), we find that the bending fluctuation part scales with the intermembrane separation \( d \) as \( d^{-2} \) for \( d \ll \sqrt{S} \) but crosses over to \( d^{-1} \) scaling for \( d \gg \sqrt{S} \), whereas the zero-mode part of the steric potential always scales as \( d^{-2} \). For membranes interacting exclusively via the steric potential, we obtain closed-form expressions for the effective interaction potential and for the rms undulation amplitude \( \sigma \), which becomes small at low temperatures \( T \) and/or large bending stiffnesses \( \kappa \). Moreover, \( \sigma \) scales as \( d \) for \( d \ll \sqrt{S} \) but saturates at \( \sqrt{\kappa T S / \kappa} \) for \( d \gg \sqrt{S} \).

In addition, using variational Gaussian theory, we apply our self-consistent treatment to study intermembrane interactions subject to different types of potentials: (i) the Moreira-Netz potential for a pair of strongly charged membranes with an intervening solution of multivalent counterions, (ii) an attractive square well, (iii) the Morse potential, and (iv) a combination of hydration and van der Waals interactions.

I. INTRODUCTION

Lipid membranes are two-dimensional fluids lacking in-plane shear elasticity, and the only elastic penalty they experience comes from changes in curvature [1]. Thus, they undergo vigorous thermally activated undulations, and a pair of such membranes brought into proximity will experience an osmotic pressure generated by the reduction of phase space available for the membranes to fluctuate. The problem of determining this osmotic pressure is a classic one, e.g., Refs. [3–13]). A major difficulty that has dogged research and functional renormalization group (FRG) techniques (see, e.g., Refs. [5–7,16]), is that a pair of membranes may not penetrate each other. One response was to replace the constraint that they do not interpenetrate. We implement the steric constraint via an exact functional integral representation and, through the use of a saddle-point approximation, transform it into a novel effective steric potential. The steric potential is found to consist of two contributions: one generated by zero-mode fluctuations of the membranes and the other by thermal bending fluctuations. For membranes of cross-sectional area \( S \), we find that the bending fluctuation part scales with the intermembrane separation \( d \) as \( d^{-2} \) for \( d \ll \sqrt{S} \) but crosses over to \( d^{-1} \) scaling for \( d \gg \sqrt{S} \), whereas the zero-mode part of the steric potential always scales as \( d^{-2} \). For membranes interacting exclusively via the steric potential, we obtain closed-form expressions for the effective interaction potential and for the rms undulation amplitude \( \sigma \), which becomes small at low temperatures \( T \) and/or large bending stiffnesses \( \kappa \). Moreover, \( \sigma \) scales as \( d \) for \( d \ll \sqrt{S} \) but saturates at \( \sqrt{\kappa T S / \kappa} \) for \( d \gg \sqrt{S} \).

In the foregoing paragraph we have described the problem of the steric potential generated purely by the thermal undulations of a pair of membranes and the hard-wall constraint. In more realistic systems (including those of biological interest), the steric potential is modified by the presence of other interactions, both short and long range, and these may include van der Waals, electrostatic (if the membranes are charged), charge regulation, and/or hydration forces. Problems of relevant concern include: (i) What is the behavior or form of the effective interaction potential? (ii) How does the equilibrium intermembrane separation change as a function of external osmotic pressure? (iii) In the case where the interaction is attractive at long range but repulsive at short range, is there an unbinding transition at zero external osmotic pressure? If so, what is the order of the unbinding transition and the threshold value of the (attractive) interaction strength for the membranes to unbind? Besides the presence of additional interactions in real systems, the membranes themselves can be multi-component, e.g., consist of a mixture of lipids and lateral inclusions that may undergo phase separation [15], and the solution may also contain polymers (such as proteins) which then interact with the membranes and anchor or adsorb onto the membrane surfaces [16].

Theoretical treatments of such problems have traditionally fallen into four classes: mean-field or Flory-Huggins-type approaches (see, e.g., Refs. [15,17–19]), variational Gaussian approximation (VGA) schemes (see, e.g., Refs. [5–7,16]).
FRG-based methods (see, e.g., Refs. [12,20–27]), and Monte Carlo simulations of different flavors (see, e.g., Refs. [28–33]). For the simpler case of a pair of single-component membranes interacting via a direct potential that consists of a long-range attractive van der Waals tail and a short-range repulsive hydration potential, mean-field theory (MFT) based on the simple addition of the direct potential with the fluctuation-induced steric potential predicts a first-order unbinding transition at a critical strength of the Hamaker coefficient \( W = W_c \). This is a Flory-Huggins-type theory, modeled after the van der Waals theory [17], whereas a Flory-potential predicts a first-order unbinding transition at a critical strength of the direct potential with the fluctuation-induced steric potential.

For the simpler case of a pair of single-component membranes interacting via a direct potential that consists of a long-range attractive van der Waals tail and a short-range repulsive hydration potential, mean-field theory (MFT) based on the simple addition of the direct potential with the fluctuation-induced steric potential predicts a first-order unbinding transition at a critical strength of the Hamaker coefficient \( W = W_c \) and scaling behavior \( d \sim |W - W_c|^{-1} \) [18]. Such an unbinding transition in three spatial dimensions has also been predicted by FRG-based calculations [20,21]. On the other hand, experimental reports that the unbinding transition in lipid bilayer systems is of first order (see, e.g., Refs. [34–37]) have been more numerous than those that report the unbinding transition to be of second order (see, e.g., Ref. [38]).

Using an approach based on a self-consistent treatment of the hard-wall constraint, we revisit the problems described in the foregoing paragraphs. The requirement of self-consistency is realized by implementing the hard-wall constraint at the level of the partition function via the use of the Heaviside function. By making use of a representation first proposed by Panyukov and Rabin [39] in a rather different context, the steric constraint can be transformed into terms of an effective interaction Hamiltonian. By considering small undulations of the membrane, we derive closed-form self-consistent expressions for the mean-square fluctuation \( \sigma^2 \) and the equilibrium intermembrane separation distance, which precisely describe how the strength of fluctuations is related to both temperature \( T \) and the curvature stiffness \( \kappa \) of the fluctuating membrane [1], as well as the average intermembrane separation distance \( d \).

This effective Hamiltonian also enables one to see the precise mechanism in which the fluctuation osmotic pressure emerges from fluctuation and steric forces, and shows a crossover of scaling behavior from \( \sigma^2 \sim k_BT/\kappa d^2 \), when a pair of membranes are close to one another, to \( \sigma^2 \sim (k_BT/\kappa)S \) (where \( S \) denotes the transverse projected area of each membrane), when the membranes are far apart.

Our self-consistency requirement is reinforced for the case of real systems (i.e., where the direct potential now includes non-Gaussian terms stemming from electrostatic, van der Waals, charge regulation, and/or hydration interactions) by our use of the VGA. The VGA captures the fact that the magnitude of the fluctuation-induced steric potential is influenced by the direct potential and vice versa [5,6,40]. Mathematically, this translates into the problem of solving a coupled pair of (typically nonlinear) equations for the rms fluctuation amplitude and the average separation (or, more generally speaking, the fluctuation correlator of an observable and the average value of that observable). It is known that the VGA becomes exact as the codimension of the manifold (which is equal to the number of components of the vector field representing the transverse fluctuations of the manifold) tends to infinity [41].

The VGA can be regarded as being complementary to FRG techniques. The FRG is essentially an asymptotic method which has been used to study problems relevant to critical behavior and the associated scaling exponents (i.e., the “shape” of the effective interaction), addressing the limiting behavior of the interaction potential in the regions of small and large intermembrane separations. As such it is less useful as a tool for making predictions about the system’s behavior at intermediate separations, which are the typical length scales of biologically relevant systems. At such length scales there is usually a number of competing interactions of comparable strength, and the use of asymptotic methods is not of much practical value [42]. One of the primary interests in membrane biophysics is also to elucidate how the effective mesoscale intermembrane interaction, accessible via detailed osmotic stress experiments on multilamellar lipid systems [40,43–46], arises from details of more microscopic forces, an aspect that is not captured by the FRG-based methods at all. These aspects can be adequately addressed by a VGA-based approach. Moreover, the VGA-based approach is comparatively simple to implement and the physical mechanism shines through the formalism more transparently.

Among our main motivations here is also to analyze the behavior of the electrostatic correlation interaction in the strong-coupling limit [47] that has been already observed between stiff charged silica surfaces [48] and is now being investigated also in the case of soft, fluctuating membranes [46]. It seems to us important to be able to understand the difference between the experimentally measured ion correlation effect between stiff and soft interfaces and to isolate in what way the membrane fluctuations change the expected separation behavior of the strong-coupling interactions. Our analysis is the first in this direction and should be helpful to understand the experimental data when available.

Our paper is divided into the following sections. Section II introduces the problem of determining the osmotic pressure of a freely undulating membrane near a hard wall and describes how the hard-wall constraint can be transformed into effective potential terms via the Panyukov-Rabin representation. The system considered is a pair of membranes subject only to hard-wall repulsion and undergoing thermal bending fluctuations. The first main result of this section is Eq. (2.23) for the rms fluctuation amplitude of a membrane near a hard wall, which interpolates between the scaling behavior of a confined membrane at short separations and that of a freely undulating membrane at large separations. The second main result is Eq. (2.31), which expresses the steric potential as the sum of contributions from thermal bending and zero-mode fluctuations. In Sec. III, we introduce a variational method due to Feynman and Kleinert [49], which we apply to study the behavior of membranes in more realistic systems, i.e., ones that are characterized by effective interaction potentials of non-Gaussian form (specifically, an attractive square-well potential, the Morse potential, the Moreira-Netz potential, and a combination of van der Waals and hydration energies). In Sec IV we present our discussion and conclusions.

**II. MEMBRANE NEAR A HARD WALL**

The fluctuation osmotic pressure of a pair of mutually impenetrable membranes of bending stiffnesses \( \kappa_1 \) and \( \kappa_2 \) [1] is equivalent to that of a membrane of stiffness \( \kappa \equiv \kappa_1 \kappa_2 / (\kappa_1 + \kappa_2) \) near a hard (i.e., impenetrable) wall. We shall thus
consider a single membrane fluctuating near a hard wall as our prototypical system. To maintain the membrane at constant average distance from the wall, an external osmotic pressure $P$ that is equal and opposite to its fluctuation osmotic pressure has to be applied. We fix the position of the wall at the origin of the $z$ axis, and a point on the membrane shall have transverse coordinates $x = (x, y)$ and occupy a position $\ell(x_{\bot})$ on the $z$ axis. The space between the wall and the membrane could be empty or filled with electrolyte solution. The membrane’s total energy is given by
\[
\overline{H} = \int d^2x \left\{ \frac{k}{2} (\nabla_{\bot}^2 \ell(x_{\bot}))^2 + \overline{V}[\ell(x_{\bot})] \right\},
\tag{2.1}
\]
where the interaction potential is given by
\[
\overline{V}[\ell(x_{\bot})] = \overline{w}[\ell(x_{\bot})] + P \ell(x_{\bot}).
\tag{2.2}
\]
Denoting the (geometric) mean separation by $\ell_0$, defined by $\int d^2x \ell(x_{\bot}) = \ell_0$, we can write
\[
\ell(x_{\bot}) = \ell_0 + \delta \ell(x_{\bot}) = \ell_0 + \int d^2Q (2\pi)^2 e^{iQ \cdot \delta \ell_{\bot}}.
\tag{2.3}
\]
where the wave-vector integral excludes the $Q = 0$ mode and $\delta \ell_{\bot}$ are the Fourier modes of the deviation $\ell(x_{\bot})$. Very soon [cf. Eq. (2.21)] we shall see the beauty of such a decomposition that lies at the heart of the Feynman-Kleinert variational theory: The terms that are linear in fluctuation vanish from the Hamiltonian (due to the integral over the transverse projected area of the membrane), and the resulting integration over the fluctuating fields is trivially Gaussian.

There are three terms in Eqs. (2.1) and (2.2). The first is the free energy associated with bending undulation modes of the membrane. The second term $\overline{w}$ represents the direct potential between the wall and the membrane, arising from forces of electrostatic and nonelectrostatic (such as hydration) origin. In general, the direct potential has a nontrivial form and is non-Gaussian in fluctuations. The third term represents the effect of applying an external osmotic pressure $P$ on the fluctuating membrane. Experimentally, for membranes in solution the external osmotic pressure can be controlled by using the classic method of Rand and Parsegian [43], which is to vary the concentration of polymer (such as dextran [44], polyvinylpyrrolidone [45], or polyethylene glycol [46]) added to extract water from between the membranes. Theoretically, the osmotic pressure term can also be interpreted as a source field that one uses to differentiate the logarithm of $Z$ in order to obtain the equilibrium separation distance $\langle \ell_0 \rangle$.

A. Hard-wall constraint: Functional representation

The partition function of a fluid membrane near a hard wall is then given by
\[
Z = \prod_{[x_{\bot}]} \int_{-\infty}^{\infty} d(\ell(x_{\bot})) \Theta[\ell(x_{\bot})] e^{-\beta \overline{H}},
\tag{2.4}
\]
where $\beta = 1/k_B T$ and $\Theta[\ell(x_{\bot})]$ is the Heaviside function which is equal to unity if $\ell(x_{\bot}) > 0$ and zero if $\ell(x_{\bot}) < 0$. Taking up an idea in Ref. [39], we express the Heaviside function in terms of the Dirac $\delta$ function:
\[
\Theta(\ell(x_{\bot})) = \int_0^{\infty} d\Lambda \delta[\Lambda - \ell(x_{\bot})].
\tag{2.5}
\]
Next, we use a Gaussian representation for the $\delta$ function and write the Heaviside function as
\[
\Theta[\ell(x_{\bot})] = \lim_{\lambda \rightarrow 0} \int_0^{\infty} d\Lambda \frac{1}{\sqrt{2\pi \lambda^2}} e^{-\left(\frac{\Lambda - \ell(x_{\bot})}{\lambda}\right)^2}.
\tag{2.6}
\]
The limit $\lambda \rightarrow 0$ is a mathematical idealization for an “infinitely hard” wall. However, for real membranes, the boundary region is not infinitely sharp but has a certain extent which is set by the length scale of the lipid headgroup size $a$. The parameter $\lambda$ reflects the size of this boundary region. We can thus write
\[
\lambda = c a,
\tag{2.7}
\]
where $c$ depends on the microscopic details of the chemical makeup of the membrane.

By making a change of variables $\Lambda = \frac{1}{2} \Lambda^2$ and promoting a prefactor $u$ into the exponent by means of a logarithm, Eq. (2.6) can be expressed in the form
\[
\Theta[\ell(x_{\bot})] = \lim_{\lambda \rightarrow 0} \int_{-\infty}^{\infty} du \frac{1}{\sqrt{2\pi \lambda^2}} e^{f_u[\ell(x_{\bot})]},
\tag{2.8}
\]
where
\[
f_u(\ell, \ell) \equiv \frac{1}{2} \ln u^2 - \frac{\left(\frac{1}{c^{2}} - \ell^2\right)}{2\lambda^2}.
\tag{2.9}
\]
We have obtained an exact functional integral representation of the steric constraint for each point of the membrane. In contrast to $\lambda$, the variable $u$ now runs over the unbounded interval $(-\infty, \infty)$. Using Eq. (2.8), we can express the partition function in Eq. (2.4) as
\[
Z = \lim_{\lambda \rightarrow 0} \prod_{[x_{\bot}]} \int_{-\infty}^{\infty} d(\ell(x_{\bot})) \int_0^{\infty} d\Lambda(x_{\bot}) \frac{e^{f_u[\ell(x_{\bot})]}}{\sqrt{2\pi \lambda^2}} e^{-\frac{\Lambda^2}{2\lambda^2}}
\]
\[
= \lim_{\lambda \rightarrow 0} \prod_{[x_{\bot}]} \int_{-\infty}^{\infty} d(\ell(x_{\bot})) \int_{-\infty}^{\infty} du(x_{\bot}) \frac{e^{f_u[\ell(x_{\bot})]}}{\sqrt{2\pi \lambda^2}} e^{-\frac{\Lambda^2}{2\lambda^2}}
\]
\[
e^{-\int \frac{d^2Q}{(2\pi)^2} \frac{2\lambda^2}{\beta} e^{-\frac{1}{\beta} \overline{H}}}.
\tag{2.10}
\]
In the functional integral expression for $Z$, we have introduced a microscopic cut-off length scale $a$, in order to convert the sum over a two-dimensional lattice of points into an integral. The length scale $a$ is set by the size of the membrane’s molecular constituents, e.g., the diameter of the lipid headgroup.

B. Steric potential: Saddle-point approximation

Let us now make the saddle-point approximation to $e^{f_u}$. It is given by
\[
e^{f_u[\ell, \ell]} \approx \sqrt{\frac{2\pi}{\left| f_u''[\ell, \ell]\right|}} e^{f_u[\ell, \ell]},
\tag{2.11}
\]
made use of only one approximation, viz., the saddle-point through terms in an effective Hamiltonian. In Eq. (2.10), we have effectively approximate in Eq. (2.10) by its saddle-point value, viz., \( \frac{\delta \ell}{Q} \) and \( \delta \ell(x) \) are small deviations around \( \ell_0 \). In Fourier space, \( \ell_0 \) is the zero wave-vector mode and

\[
\delta \ell(x) = \sum_Q e^{iQ \cdot x} \delta \ell_Q.
\]

As \( \lambda \) is small, we can expand the above to leading order in \( \lambda \):

\[
f^{*}_{\lambda} = -\frac{\ell^2 + \ell \sqrt{\ell^2}}{4\lambda^2} - \frac{1}{4} + \frac{\sqrt{\ell^2}}{4\ell} + \frac{1}{2} \ln \left( \frac{\ell + \sqrt{\ell^2}}{2\ell} \right)
- \frac{(\ell + 5\sqrt{\ell^2})\lambda^2}{8\ell \sqrt{\ell^2}(\ell + \sqrt{\ell^2})} + \ln \lambda + O(\lambda^3),
\]

where we have neglected a constant term \( \frac{1}{2} \ln(2\pi) \). We see that terms for which \( \ell \) is negative diverge to negative infinity, and so \( e^{iQ} \) goes to zero, which reflects the zero probability of finding the membrane inside the wall.

We now focus on the case of membranes undergoing thermally excited undulations with small amplitude. Let us write \( \ell(x_{\perp}) = \ell_0 + \delta \ell(x_{\perp}) \), where \( \ell_0 \) is the geometric (not thermal) mean defined by \( \ell_0 \equiv (1/S) \int d^2x_{\perp} \ell(x_{\perp}) \), and \( \delta \ell(x_{\perp}) \) are small deviations around \( \ell_0 \). In Fourier space, \( \ell_0 \) is the zero wave-vector mode and

\[
\delta \ell(x_{\perp}) = \sum_Q e^{iQ \cdot x_{\perp}} \delta \ell_Q.
\]

where \( Q \) is a two-dimensional wave-vector conjugate to \( x_{\perp} \), and the prime denotes the exclusion of the zero wave-vector mode from the wave-vector sum. Both \( \ell_0 \) and \( \{\delta \ell_Q \} \) or \( \{\delta \ell(x_{\perp})\} \) are independent thermally fluctuating variables that take values from the interval \((-\infty, \infty)\) [cf. Eq. (2.10)]. By performing an expansion to quadratic order in \( \delta \ell(x_{\perp}) \), Eq. (2.15) becomes

\[
f^{*}_{\lambda} \approx -\frac{(\ell_0 + 5\delta \ell_0)\lambda^2}{8\ell_0 \sqrt{\ell_0^2 + \delta \ell_0^2}} + \frac{(\ell_0 + 5\delta \ell_0)\lambda^2}{4\ell_0^{3/2}(\ell_0 + \delta \ell_0)}
- \frac{(2\ell_0 + \sqrt{\ell_0^2 + \delta \ell_0^2})(\ell_0 + 5\delta \ell_0)\lambda^2}{4\ell_0^{3/2}(\ell_0 + \delta \ell_0)^2} \delta \ell^2.
\]

For negative values of \( \ell_0 \) the leading-order term of the above expression diverges to negative infinity, which means that the geometric average position of the membrane cannot move inside the wall. Under this approximation, we can effectively restrict the range of values that \( \ell_0 \) takes in the partition function to the positive interval \((0, \infty)\), and re-express Eq. (2.17) as

\[
f^{*}_{\lambda} \approx -\frac{3\lambda^2}{8\ell_0^2} + \frac{3\lambda^2}{4\ell_0^2} \delta \ell(x_{\perp}) - \frac{9\lambda^2}{8\ell_0^2} (\delta \ell(x_{\perp}))^2.
\]

We note that the term linear in \( \delta \ell(x_{\perp}) \) will vanish when we integrate over the transverse projected area. The saddle-point approximation to \( Z \) thus can be written as

\[
Z \approx \int_0^{\infty} d\ell_0 \sum_{x_{\perp}} \int_{-\infty}^{\infty} d\delta \ell(x_{\perp}) e^{-\ell_0^2} \delta \ell_{\perp}^2 + V_{\perp}(\delta \ell(x_{\perp}))^2 + V_{\perp}(\delta \ell(x_{\perp}))^2 + V_{\perp}(\delta \ell(x_{\perp}))^2 + V_{\perp}(\delta \ell(x_{\perp}))^2
\]

where \( V \) is now an effective potential defined by

\[
V = w[\ell(x_{\perp})] + P\ell(x_{\perp})
\]

and

\[
w[\ell(x_{\perp})] = \tilde{w}[\ell(x_{\perp})] + \frac{9k_BT^2}{8\ell_0^4} (\delta \ell(x_{\perp}))^2 + \frac{3k_BT^2}{8\ell_0^4} (\delta \ell(x_{\perp}))^2.
\]
In the above, we have removed a prefactor \((2\pi \lambda^2)^{-S/2\omega^2}\). This can be done, as the prefactor simply corresponds to a shift of the effective free energy by an (infinite) constant.

The prefactor of the term quadratic in \(\delta\ell\) can be interpreted as an effective compression modulus generated by the steric force acting between the membrane and the wall. The interaction potential \(w\) thus consists of two contributions: a soft potential \(\tilde{w}\) that describes the longer-range (and coarse-grained) interactions of the membranes and a hard potential which arises from the steric constraint. Such a decomposition into soft and hard contributions is possible because we are working at an already coarse-grained or mesoscopic level; otherwise all contributions (including steric effects) are reducible to electrostatic ones. By rewriting the steric constraint in terms of \(\delta\) functions [Eqs. (2.5) and 2.8] and applying a saddle-point approximation on \(u\), we were able to transform the partition function for a sterically constrained membrane into one for an unconstrained membrane, with the effects of the steric constraint accounted for by terms in an effective interaction potential \(w\) [cf. Eq. (2.21)]. This also completes the program set out in Ref. [6] but not carried out to its full implementation.

Two observations can immediately be made: (i) the energy diverges as the mean separation \(\ell_0\) tends to zero, which reflects the fact that the membrane is unable to penetrate the wall, and (ii) the prefactor of the fluctuation term also diverges as \(\ell_0 \to 0\), which reflects the fact that the fluctuations of the membrane must also be suppressed as it reaches the wall.

### C. Application: Steric and fluctuation forces

Let us consider a pair of membranes that interact via only steric and fluctuation forces. As we have already noted, the two-membrane system can be recast as a membrane interacting with a hard wall. This problem admits a closed-form solution that describes how \(\sigma^2\) depends on \(\ell_0\). We set the soft potential to \(\tilde{w} = 0\). The hard-wall and fluctuation-induced repulsion from the wall has to be balanced by an external osmotic pressure if the membrane is to remain at a finite distance from the wall. For the potential including only the sterically generated interactions, Eq. (2.21) assumes the form

\[
w[\ell(x_L)] = \frac{9k_BTc^2}{8\ell_0^2} [\delta(\ell(x_L))]^2 + \frac{3k_BTc^2}{8\ell_0^2},
\]

(2.22)

The functional integration over \(\delta\ell\) in \(Z\) is thus Gaussian and readily can be performed. Using Eq. (2.19) and the definition \(\sigma^2 \equiv \langle [\delta(\ell(x_L))]^2 \rangle_{\delta\ell}\) (where \(\langle \ldots \rangle_{\delta\ell}\) denotes averaging over \(\delta\ell\) using \(Z\) for a given \(\ell_0\)) yields for the mean-square fluctuation amplitude [cf. also Eq. (3.9)]

\[
\sigma^2 = \frac{\ell_0^2}{12c} \sqrt{\frac{k_BT}{k}} \left[ 1 - \frac{2}{\pi} \tan^{-1} \left( \frac{2\ell_0^2}{3\pi c} \sqrt{\frac{k}{k_BT}} \right) \right].
\]

(2.23)

Comparing with the ansatz \(\sigma^2 = \mu d^2\) of Ref. [2] (where \(d = \ell_0\)), we see that \(\mu\) has the following structure:

\[
\mu = \frac{1}{12c} \sqrt{\frac{k_BT}{k}} \left[ 1 - \frac{2}{\pi} \tan^{-1} \left( \frac{2\ell_0^2}{3\pi c} \sqrt{\frac{k}{k_BT}} \right) \right].
\]

(2.24)

In accordance with the expectations described in the Introduction, our calculation has revealed the structure behind the prefactor \(\mu\), showing it to be a nonlinear function of \(k_BT/k\) and \(\ell_0/\sqrt{S}\). To understand the properties of \(\mu\), we look at two limiting cases: the regimes of small and large intermembrane separations. Defining the dimensionless variables \(\tilde{\ell}_0 \equiv \ell_0/d^*\) and \(\tilde{\sigma} \equiv \sigma/d^*\), where \(d^* \equiv \sqrt{3c(k_BT)^{1/4} / (4\pi c)^{1/4}}\), the above equation can be put in dimensionless form:

\[
\tilde{\sigma}^2 = \frac{1}{12c} \sqrt{\frac{k_BT}{k}} \left[ 1 - \frac{2}{\pi} \tan^{-1} \left( \frac{2\ell_0^2}{3\pi c} \sqrt{\frac{k}{k_BT}} \right) \right].
\]

(2.25)

At separations small compared with the linear dimension of the membrane, viz., \(\ell_0 < \sqrt{3c(k_BT/4\pi c)^{1/4} / \sqrt{S}}\), there is a crossover to the behavior of a single, free membrane:

\[
\sigma^2 \approx \frac{k_BT S}{4\pi \mu c}.
\]

(2.26)

This formula has the same scaling dependence on separation as the one originally postulated by Helfrich, but here we have derived the scaling dependence rather than postulated it. From our result we see that the fluctuations become small at low temperature and/or large membrane curvature modulus.

On the other hand, for two membranes that are more widely separated than the linear dimension of either membrane, viz., \(\ell_0 > \sqrt{3c(k_BT/4\pi c)^{1/4} / \sqrt{S}}\), there is a crossover to the behavior of a single, free membrane:

\[
\sigma^2 \approx \frac{k_BT S}{4\pi \mu c}.
\]

(2.27)

At large separations, each membrane would behave as if there is no hard-wall potential present, and the mean-square fluctuation of each membrane is then set by its total area.

The free energy per unit area \(f_s\), for a given average separation \(\ell_0\) and external osmotic pressure \(P\) is given by \(f_s = -\ln Z\). The functional integration over the fluctuation modes \(\delta\ell_Q\) in Fourier space is Gaussian and yields

\[
f_s = P\ell_0 + \frac{3k_BTc^2}{8\ell_0^2} + \frac{k_BT}{2} \int \Delta^2Q \ln \left( 1 + \frac{9k_BTc^2}{4\kappa \ell_0^4 \Delta^4} \right). \]

(2.28)

In the above calculation, we have subtracted off a constant background contribution to \(f_s\) coming from \(\ell_0 \to \infty [50]\). Taking the upper bound of the momentum integral to be \(\infty\) and the lower bound to be \(1/\sqrt{S}\), we obtain a closed-form expression for \(f_s\):

\[
f_s = P\ell_0 + \frac{3k_BTc^2}{8\ell_0^2} - \frac{k_BT}{8\pi S} \ln \left( 1 + \frac{9k_BTc^2S^2}{4\kappa \ell_0^4} \right)
+ \frac{k_BT}{4\pi} \sqrt{\frac{9k_BTc^2}{4\kappa \ell_0^4}} \tan^{-1} \left[ 1 - \frac{\sqrt{2(4\pi k)^{1/4} \ell_0}}{(9k_BTc^2)^{1/4} / \sqrt{S}} \right]
+ \tan^{-1} \left[ 1 + \frac{\sqrt{2(4\pi k)^{1/4} \ell_0}}{(9k_BTc^2)^{1/4} / \sqrt{S}} \right].
\]

(2.29)

We can consider the far- and near-field behaviors of \(f_s\). The far-field regime is described by \(\ell_0 \gg \sqrt{3c(k_BT/4\pi c)^{1/4} / \sqrt{S}}\). To order \(S^3\ell_0^{-8}\), \(f_s\) is given by

\[
f_s \approx P\ell_0 + \frac{3k_BTc^2}{8\ell_0^2} + \frac{9(k_BT)^2c^2S}{32\pi k \ell_0^4} + \frac{27(k_BT)^3c^4S^3}{128\pi k^2 \ell_0^8}.
\]

(2.30)
In the near-field regime, \( \ell_0 \ll \sqrt{3c(k_B T/4\kappa)^{1/4}\sqrt{S}} \). To order \( S^{-1} \), \( f_s \) is given by

\[
f_s \approx \frac{3k_B Tc}{16\ell_0^3} \sqrt{\frac{k_BT}{\kappa}} + \frac{3k_B Tc^2}{8\ell_0^5} + P\ell_0^3
- \frac{k_BT}{4\pi S} \left[ 1 + \ln \left( \frac{3c\sqrt{k_BT}S}{2\sqrt{\kappa}\ell_0^3} \right) \right].
\] (2.31)

Equations (2.30) and (2.31) indicate that the steric potential has two contributions: one that comes from thermal fluctuations of the zero mode (i.e., \( \ell_0 \)), represented by the second term in Eq. (2.30) and in Eq. (2.31), and another that is induced by thermal bending fluctuations of the membrane [i.e., \( \delta \ell(x_1, \ldots) \)], represented by the third and fourth terms in Eq. (2.30) and the first and last terms in Eq. (2.31). Note that as \( \ell_0 \) is varied from small to large values, the bending fluctuation contribution to the steric potential changes its scaling form from \( \ell_0^2 \) to \( \ell_0^4 \) and is thus much weaker at large separations.

In the near-field regime, to zeroth order in \( S^{-1} \), we can compare our result above with the picture of Ref. [2], where the free-energy cost of thermal bending fluctuations of steric membranes is described via the term \( V_H = c_0(k_BT)^2/\kappa \ell_0^3 \); in keeping with the literature we call \( V_H \) the Helfrich interaction. In the Helfrich interaction term, \( c_0 \) is regarded as a universal number (see, e.g., Refs. [2,13]). One may regard the first term of Eq. (2.31) as being the analog of the Helfrich interaction [51]. However, one should note an important distinction: for \( \kappa \to \infty \), \( V_H \) goes to zero, and the Helfrich term thus does not address the case of osmotic pressure generated by longitudinally fluctuating flat membranes (i.e., zero-mode fluctuations) and therefore describes only the bending fluctuation “decoration” about a flat membrane but not the longitudinal fluctuation of the flat membrane itself.

As the intervening region between the membranes is free to exchange volume with the surrounding reservoir while being subject to a constant external osmotic pressure \( P \), the system behavior is best described using a constant osmotic pressure ensemble, where the equilibrium separation \( \langle \ell_0 \rangle \) is determined according to

\[
\langle \ell_0 \rangle = \frac{1}{Z} \int_0^\infty d\ell_0 \ell_0 e^{-\beta S} = -\frac{T}{S} \frac{\partial \ln Z}{\partial P}.
\] (2.32)

The equilibrium separation can be estimated in the saddle-point approximation by looking for the minimum of \( f_s \) with respect to variations in \( \ell_0 \). Defining the dimensionless variables \( \tilde{\ell}_0 \equiv \ell_0/d^* \), \( \tilde{P} \equiv P(d^*)^3 \), \( \tilde{S} \equiv S/(d^*)^2 \), and \( \alpha \equiv 3c\sqrt{k_BT}/4\pi \sqrt{\kappa} \), where \( d^* = \sqrt{3c(k_BT)^{1/2}/\sqrt{S}}(4\kappa)^{1/4} \), we can recast Eq. (2.29) in dimensionless form:

\[
\tilde{f}_s \equiv \beta(d^*)^3 f_s
= \tilde{P}\tilde{\ell}_0 + (3c/\beta)\tilde{\ell}_0^{-2} - \frac{\alpha}{2} \ln \left( 1 + \tilde{\ell}_0^{-4} \right)
+ \alpha\tilde{\ell}_0^{-2} \left[ \tan^{-1}(1 - \sqrt{2}\tilde{\ell}_0) + \tan^{-1}(1 + \sqrt{2}\tilde{\ell}_0) \right].
\] (2.33)

The stationarity condition \( \partial \tilde{f}_s/\partial \tilde{\ell}_0 = 0 \) then leads to

\[
\tilde{P} = \frac{3c}{2} + 2\alpha \left[ \tan^{-1}(1 - \sqrt{2}\tilde{\ell}_0) + \tan^{-1}(1 + \sqrt{2}\tilde{\ell}_0) \right] / (\tilde{\ell}_0^3),
\] (2.34)

where \( \tilde{\ell}_0^* \) is the saddle-point approximation to the equilibrium separation \( \langle \ell_0 \rangle \). In the near-field limit \( (\tilde{\ell}_0^*) \ll 1 \), we have to leading order

\[
\tilde{P} \approx \frac{3c}{4}\left( \frac{1}{2} \sqrt{\frac{k_BT}{\kappa}} + c \right) (\tilde{\ell}_0^*)^{-3}.
\] (2.35)

Restoring dimensions, we have

\[
\langle \ell_0 \rangle \approx (k_BT)^{1/3} \left[ \frac{3c}{4} \left( \frac{1}{2} \sqrt{\frac{k_BT}{\kappa}} + c \right) \right]^{1/3} P^{-1/3}.
\] (2.36)

Thus, the equilibrium separation diverges as \( P^{-1/3} \) as \( P \to 0 \) and vanishes as \( T \to 0 \) (the pair of membranes simply collapse onto each other at zero temperature) as one would expect.

In the far-field regime \( (\tilde{\ell}_0^*) \gg 1 \), we have to the order of \( (\tilde{\ell}_0^*)^{-4} \),

\[
\tilde{P} \approx \frac{3c^2}{4(\tilde{\ell}_0^*)^3} + \frac{3c\sqrt{k_BT}}{4\pi}(\tilde{\ell}_0^*)^{-5}.
\] (2.37)

The equilibrium separation increases monotonically with decreasing osmotic pressure.

The behaviors of \( \tilde{\ell}_0^* \) and \( \tilde{\ell}_0^* \) are plotted in Fig. 2. The rms fluctuation amplitude vanishes at zero intermembrane separation (reflecting the hard-wall constraint), scales linearly with the intermembrane separation for small values of the separation, and saturates at a constant value set by the cross-sectional area of the membrane for large values of the separation.

III. FEYNMAN-KLEINERT VARIATIONAL APPROXIMATION

In the previous section we derived an effective Hamiltonian [Eq. (2.21)] which accounts for the steric constraint via the hard potential, and applied it to study a membrane interacting with a hard wall via only Helfrich and steric forces. We were able to obtain closed-form expressions for the rms fluctuation amplitude and free energy per unit area of the membrane [cf. Eqs. (2.23) and (2.29)] because for such interactions the
form of the effective Hamiltonian is Gaussian. In realistic systems the soft potential rarely has a Gaussian form, and further approximations will have to be made on the partition function. One such approximation is the Feynman-Kleinert (FK) variational approximation [49], developed originally for the quantum-mechanical partition function of an anharmonic oscillator, but can equally well be applied to the classical-partition function of thermally fluctuating membranes [6].

The application of the variational approximation [52] begins with a trial partition function $Z_1$ that is Gaussian in fluctuations $\delta \ell$, viz.,

$$Z_1 = \int_0^\infty d\ell_0 \prod_{[\ell_1]} \int_{-\infty}^\infty d\delta \ell(\mathbf{x}_1)e^{-\beta \int d^2 x_1 \left( \frac{1}{2} \left[ \frac{\delta \ell}{\delta \ell} \right] + V_{\text{trial}} \right) + \mathbf{v}_{\text{trial}}},$$

where

$$V_{\text{trial}} = \frac{1}{2} B \left[ \delta \ell(\mathbf{x}_1) \right]^2 + w_0(\ell_0) + P \ell(\mathbf{x}_1).$$

The variational principle relies on Jensens' inequality, viz.,

$$Z > e^{-\beta(V-V_{\text{trial}})} Z_1,$$

where the notation $\langle \ldots \rangle_1$ denotes Boltzmann averaging with respect to the statistics of both $\ell_0$ and $\{\delta \ell(\mathbf{x}_1)\}$ specified by $Z_1$. The best estimate is obtained by looking for the maximum upper bound on the right-hand side. There are two unknowns: (i) an unknown parameter $B$, which is related to the mean-square fluctuation of the membrane, and (ii) an unknown function $w_0$. The form of $w_0$ is fixed in terms of $B$ by requiring that

$$(V - V_{\text{trial}})_{1} = 0.$$

The unknown parameter $B$ is then determined by optimizing $Z_1$.

To see how the FK variational approximation works in the context of fluctuating membranes, let us define a restricted trial partition function $Z_\sigma$, viz.,

$$Z_\sigma = \prod_{[\ell_1]} \int_{-\infty}^\infty d\delta \ell(\mathbf{x}_1)e^{-\beta \int d^2 x_1 \left( \frac{1}{2} \left[ \frac{\delta \ell}{\delta \ell} \right] + V_{\text{trial}} \right) + \mathbf{v}_{\text{trial}}},$$

and the associated average $\langle \ldots \rangle_\sigma$, viz.,

$$\langle \ldots \rangle_\sigma = \frac{\prod_{[\ell_1]} \int_{-\infty}^\infty d\delta \ell(\mathbf{x}_1) \ldots e^{-\beta \int d^2 x_1 \left( \frac{1}{2} \left[ \frac{\delta \ell}{\delta \ell} \right] + V_{\text{trial}} \right) + \mathbf{v}_{\text{trial}}}}{\prod_{[\ell_1]} \int_{-\infty}^\infty d\delta \ell(\mathbf{x}_1)e^{-\beta \int d^2 x_1 \left( \frac{1}{2} \left[ \frac{\delta \ell}{\delta \ell} \right] + V_{\text{trial}} \right) + \mathbf{v}_{\text{trial}}}}.$$

By using Eqs. (2.20), (3.2), and (3.4), we obtain

$$Z_\sigma \prod_{[\ell_1]} \int_{-\infty}^\infty d\delta \ell(\mathbf{x}_1) (V - V_{\text{trial}}) e^{-\beta \int d^2 x_1 \left( \frac{1}{2} \left[ \frac{\delta \ell}{\delta \ell} \right] + V_{\text{trial}} \right) + \mathbf{v}_{\text{trial}}} = 0$$

$$\Rightarrow w_0(\ell_0) = w_{\sigma_1}(\ell_0) - \frac{B}{2} \sigma^2,$$

where the variational estimates of the mean-square fluctuation $\sigma^2$ and the interaction energy $w_{\sigma_1}$ are defined by

$$\sigma^2 = \langle (\delta \ell(\mathbf{x}_1))^2 \rangle_\sigma;$$

$$w_{\sigma_1}(\ell_0) \equiv \langle w(\ell) \rangle_\sigma.$$

We compute the mean-square fluctuation:

$$\sigma^2 = \frac{k_B T}{8 \sqrt{\kappa B}} \left[ 1 - \frac{2}{\pi} \tan^{-1} \left( \frac{1}{\sqrt{\kappa/B}} \right) \right].$$

In the above calculation, we have made use of the continuum representation of the wave-vector sum, $S^{-1} \sum_{\mathbf{q}} \rightarrow \int \frac{d^2 \mathbf{q}}{(2\pi)^2}$, and restricted the wave-vector sum to those wave vectors that are positive, the reason being that $\delta \ell(\mathbf{x}_1)$ is real and thus the components $\delta \ell^\alpha_{\mathbf{q}}$ (and $\delta \ell^\alpha_{-\mathbf{q}}$) are not independent: $\delta \ell^\alpha_{\mathbf{q}} = \delta \ell^\alpha_{-\mathbf{q}}$ and $\delta \ell^\alpha_{\mathbf{q}} = \delta \ell^\alpha_{-\mathbf{q}}$. In the second line of Eq. (3.9), we have included a correction term due to the finite size of the membrane. In the limit of an infinitely large membrane (which effectively means that the square root of the membrane’s projected cross-sectional area is much greater than the intermembrane separation), the above result simplifies to

$$\sigma^2 = \frac{k_B T}{8 \sqrt{\kappa B}}$$

and

$$B = \frac{\left( k_B T \right)^2}{6 \kappa \sigma^4}.$$
\[ Z_1 = \int_0^\infty d\ell_0 e^{-\beta S_{\text{var}}} = \int_0^\infty d\ell_0 Z_\sigma. \] (3.13)

To determine the variational free energy, we first express Eqs. (3.1) and (3.2) in Fourier space:

\[ Z = \prod_{Q \neq 0} \int d\delta \tilde{Q} e^{-\beta S[Q(0,0)+\delta]} e^{-\beta S}\langle Q(0,0)+\delta \rangle^2 \]
\[ = \prod_{Q \neq 0} \left( \frac{\pi k_B T}{\kappa Q^4 + B} \right) = e^{\frac{1}{2} \sum_{Q \neq 0} \ln \frac{\pi^2 \kappa Q^2}{\kappa Q^2 + B}} \]
\[ \text{regulate} \quad e^{\frac{1}{2} \langle \tilde{Q}^2 \rangle \ln \frac{\pi^2 \kappa Q^2}{\kappa Q^2 + B}} = e^{-\frac{1}{2} \sqrt{\beta S}}. \] (3.15)

The regularization subtracts off the constant (and divergent) contribution of membranes that are infinitely far apart [50]. Equation (3.14) thus becomes

\[ Z_1 = \int d\ell_0 e^{-\beta S[Q(0,0)+\delta]} e^{-\frac{1}{2} \sqrt{\beta S}}. \] (3.16)

Substituting for \( w_{\ell_0}(Q) \) its value from Eq. (3.7) and using Eqs. (2.21) and (3.8b), we obtain

\[ Z_1 = \int d\ell_0 e^{-\beta S[Q(0,0)+\delta]} e^{-\frac{1}{2} \sqrt{\beta S}} \]
\[ = \prod_{Q \neq 0} \left( \frac{\pi k_B T}{\kappa Q^4 + B} \right) = e^{\frac{1}{2} \sum_{Q \neq 0} \ln \frac{\pi^2 \kappa Q^2}{\kappa Q^2 + B}} \]
\[ \text{or, equivalently, from Eqs. (3.10) and (3.11),} \]
\[ Z_1 = \int d\ell_0 e^{-\beta S[Q(0,0)+\delta]} e^{-\frac{1}{2} \sqrt{\beta S}} \]
\[ = \prod_{Q \neq 0} \left( \frac{\pi k_B T}{\kappa Q^4 + B} \right) = e^{\frac{1}{2} \sum_{Q \neq 0} \ln \frac{\pi^2 \kappa Q^2}{\kappa Q^2 + B}} \]
\[ \text{Comparing with Eq. (3.13), we see that the variational free energy per unit area is given by} \]
\[ f_{\text{var}} = \frac{(k_B T)^2}{128\kappa \sigma^2} + \frac{9k_B T^2 \sigma^2}{8\ell_0^2} + \frac{3k_B T^2}{8\ell_0^2} + \frac{9k_B T^2 \sigma^2}{8\ell_0^2} + w_{\ell_0}^2 + P\ell_0. \] (3.19)

In the language of Ref. [26], the first three terms can be regarded as comprising a repulsive fluctuation potential. The fourth term is a fluctuation-renormalized version of the direct potential, and thus \( f_{\text{var}} \) cannot be simply regarded as a sum of fluctuation and direct potentials. The additive sum would be valid in the so-called weak fluctuation regime, defined by Ref. [26] to be one in which the attractive tail of the direct potential is stronger than the repulsive fluctuation potential.

On the other hand, \( f_{\text{var}} \) is not applicable to the strong fluctuation regime, defined to be one in which the fluctuation potential is stronger than the attractive tail of the direct potential, because in such a regime the fluctuations are strongly nonlinear and the Gaussian approximation assumed by the VGA is no longer reliable. The VGA-based \( f_{\text{var}} \) thus applies to a regime intermediate between the weak and strong fluctuation regimes, which as already stated, is exactly the regime we want to address.

To obtain a relation between \( \sigma^2 \) and \( \ell_0 \), we vary \( f_{\text{var}} \) with respect to \( \sigma^2 \); this yields

\[ \frac{\partial w_{\ell_0}}{\partial \sigma^2} = \frac{(k_B T)^2}{128\kappa \sigma^2} + \frac{9k_B T^2 \sigma^2}{8\ell_0^2} = 0. \] (3.20)

This can be rewritten in the form

\[ \frac{\partial w_{\ell_0}}{\partial \sigma^2} = \frac{1}{2} B - \frac{9k_B T^2 \sigma^2}{8\ell_0^2}, \] (3.21)

which is similar to Eq. (17) of Ref. [6], with the extra contribution coming from the steric potential.

The equilibrium value of \( \ell_0 \) for a given external osmotic pressure \( P \) is defined by

\[ \langle \ell_0 \rangle = \frac{1}{Z_1(P)} \int_0^\infty d\ell_0 e^{-\beta S_{\text{var}}(P)}. \] (3.22)

The equilibrium separation \( \langle \ell_0 \rangle \) is thus a function of \( P \). We invert the above relation to determine how \( P \) depends on \( \langle \ell_0 \rangle \), which gives the equation of state. For this one generally has to resort to numerical means. On the other hand, one can approximate \( \langle \ell_0 \rangle \) by its saddle-point value \( \ell_0^* \), obtained by minimizing \( f_{\text{var}} \) over \( \ell_0 \):

\[ \frac{\partial f_{\text{var}}}{\partial \ell_0} \bigg|_{\ell_0^*} = 0. \] (3.23)

This relation yields \( \ell_0^* \) as a function of the external osmotic pressure \( P \). To summarize: In the Feynman-Kleinert approach, one decomposes the thermally fluctuating field into two types of contributions, a zero-mode contribution \( \ell_0 \) and a finite wave-vector contribution \( \delta \ell_0 \) \( Q \neq 0 \), and approximates \( \sigma^2 \) by means of a Gaussian kernel but retains the full nonlinear dependence of the free energy on \( \ell_0 \) (present in \( \bar{w}_{\ell_0} \)), which is then minimized over \( \ell_0 \). This leads to an improved accuracy over that of the more conventional form of VGA [52], which approximates both the thermal equilibrium average of an observable and its mean-square fluctuation by means of a Gaussian kernel.

A. Applications

In what follows, we apply our formalism and the variational approach developed in previous sections to study the physical behavior of four different model membrane systems in the regime where \( \ell_0 \ll \sqrt{\kappa} \).

First, we analyze a system consisting of equally charged impenetrable membranes, with an intervening solution of multivalent counterions, assuming that the surface charge density is sufficiently large so the system is in the strong-coupling (SC) regime of electrostatics [53–56]. In this regime, for the case of two planar, infinitely rigid membranes, the osmotic pressure decomposes into a simple sum of two contributions: one describing the entropy reduction of each counterion and another describing the electrostatic interaction between the counterion and a charged membrane. We will call the interaction potential of such a system the Moreira-Netz potential.
Our second system has for its interaction potential an attractive square well, which is a model for describing the adhesion of membranes by short-range attractive forces, studied, e.g., in Ref. [31].

In our third system, the direct interaction is modeled by a Morse potential which has been used in studies of biological membrane systems and interactions of DNA molecules in solution [7,57,58]. The Morse potential consists of a repulsive exponential term which mimics the hydration and excluded volume repulsion of the membranes and an attractive exponential term (with twice the decay width of the repulsive term) which mimics the attractive long-range tail.

Finally, we consider a system consisting of two membranes interacting via a generic soft potential consisting of a hydration term and a van der Waals term approximated in the nonretarded planar limit [17,40].

1. Moreira-Netz potential

Let us first consider the case of a pair of strongly charged membranes in solution with counterions of valence q in the intervening region of charge sign opposite to the charge on the membranes. As the membranes are strongly charged, the system is in what is known as the strong-coupling (SC) regime [53–56], where Poisson-Boltzmann (PB) theory and its fluctuation-corrected version break down. The SC regime is characterized by a pair of unit charges at a given temperature \( T \).

As the membranes are strongly charged, the system is in what is known as the strong-coupling (SC) regime [53–56], where Poisson-Boltzmann (PB) theory and its fluctuation-corrected version break down. The SC regime is characterized by a pair of unit charges at a given temperature \( T \). The regime for which PB theory holds is known as the weak-coupling regime [53–56].

The variational free energy per unit area is then given by [cf. Eq. (3.19)]

\[
\beta f_{\text{var}} = \frac{k_B T}{128 \pi \sigma_0^3} + \frac{9 q^2 \sigma_0^2}{8 \ell_0^2} + \frac{3 c^2}{8 \ell_0^2} + \beta P \ell_0 - 4 \pi \mu \ell_0 \sigma_0^2 \left( \ln \frac{\ell_0}{2 \mu} - \frac{\ell_0}{2 \mu} - \frac{\sigma_0^2}{2 \ell_0^2} \right).
\]

(3.25)

In the second step, we have Taylor expanded the logarithm to quadratic order in \( \delta \ell(x_L) \). On applying the Gaussian approximation of Eq. (3.12), we obtain

\[
\beta \tilde{w}_{\sigma^2}(\ell_0) = -4 \pi \mu \ell_0 \sigma_0^2 \left( \ln \frac{\ell_0}{2 \mu} - \frac{\ell_0}{2 \mu} - \frac{\sigma_0^2}{2 \ell_0^2} \right).
\]

(3.26)

The variational free energy per unit area is then given by [cf. Eq. (3.19)]

\[
\beta f_{\text{var}} = \frac{k_B T}{128 \pi \sigma_0^3} + \frac{9 q^2 \sigma_0^2}{8 \ell_0^2} + \frac{3 c^2}{8 \ell_0^2} + \beta P \ell_0 - 4 \pi \mu \ell_0 \sigma_0^2 \left( \ln \frac{\ell_0}{2 \mu} - \frac{\ell_0}{2 \mu} - \frac{\sigma_0^2}{2 \ell_0^2} \right).
\]

(3.27)

where \( P \) is the external osmotic pressure applied to keep the membranes at a constant average separation.

Varying \( f_{\text{var}} \) with respect to \( \sigma \) we obtain

\[
\sigma^2 = \left( 1 + \frac{8 \sigma_0^2 \ell_0^2}{9 c^2 q} \right)^{-1/2} \frac{k_B T}{\kappa} \frac{\ell_0^2}{12 c}.
\]

(3.28)

To form dimensionless variables, let us rescale \( \sigma \) and \( \ell_0 \) in units of \( \mu_0 \equiv q \mu \) (since the Gouy-Chapman length \( \mu \) varies as \( q^{-1} \); we are interested in the effect of varying the valence \( q \), so the basic length scale should be independent of \( q \)). Let us also define dimensionless variables \( t \equiv k_B T / \kappa \), \( \ell_0 \equiv \ell_0 / \mu_0 \), \( \sigma^2 \equiv \mu_0 \sigma_0^2 \), and \( \beta \equiv \beta / \mu_0 \), whence the above equation can be put in the form

\[
\sigma^2 = \left( 1 + \frac{8 \sigma_0^2 \ell_0^2}{9 c^2 q} \right)^{-1/2} \frac{k_B T}{8 \ell_0^2}.
\]

(3.29)

This formula holds strictly for the SC regime where \( \Sigma \gg 1 \). Substituting the value of \( \sigma^2 \) into our expression for \( f_{\text{var}} \) yields \( f_{\text{soft}} \), the effective interaction energy between two “soft” surfaces:

\[
\beta f_{\text{soft}} = \frac{3 c}{16 \ell_0^2} \frac{k_B T}{8 \ell_0^2} \left( 1 + \frac{8 \sigma_0^2 \ell_0^2}{9 c^2 q} \right) \frac{1}{\kappa} + \frac{3 c^2}{8 \ell_0^2} - 4 \pi \mu \ell_0 \sigma_0^2 \left( \ln \frac{\ell_0}{2 \mu} + \frac{\ell_0}{2 \mu} \right).
\]

(3.30)

The system still needs to be equilibrated with respect to \( \ell_0 \). Let us define the dimensionless variables: \( \ell_0 \equiv \ell_0 / \mu_0 \) and \( \bar{\sigma} \equiv \beta P / 4 \pi \ell_0 \sigma_0^2 \). Equation (3.30) then becomes

\[
\tilde{f}_{\text{soft}}(\bar{\ell}_0) = q \left( \frac{\bar{\sigma}}{2} + \frac{3 q c^2}{16 \ell_0^2} \right) \left( \frac{1}{\bar{\sigma}} \right) + \frac{3 q c^2}{32 \ell_0^2} \left( \frac{1}{\bar{\sigma}} \right)^2.
\]

(3.31)
where \( \tilde{\sigma} \equiv \beta f / 4 \pi \mu \ell_B \sigma^2 \). In the saddle-point approximation, the equilibrium separation \( \tilde{\ell} \) is given by the solution to the equation \( \partial \tilde{F}_{\text{osm}}(\tilde{\ell}_0)/\partial \tilde{\ell}_0 = 0 \). We obtain

\[
\tilde{\ell} = \frac{1}{\ell^*} - \frac{q}{2} + \frac{3qc^2}{8\tilde{\sigma}^2(\ell^*)^3} - \frac{\sqrt{t}}{12c\ell^*} \left\{ \frac{R_c^2\tilde{\sigma}^2}{8c^2q} + 1 \right\}
\]

The last three terms on the right-hand side of Eq. (3.32) describe corrections to the equilibrium separation induced by the thermal fluctuations of the membrane.

In Fig. 3, we display a plot of \( \tilde{\ell} \) as a function of \( \tilde{p} \) for the case of thermally fluctuating membranes, where we have also plotted the case of fixed charged plates for comparison. In the inset we show the behavior of \( \tilde{\sigma} \equiv \sigma / \mu_0 \) as a function of \( \tilde{\ell} \) for thermally fluctuating membranes. The behaviors are plotted for \( t = 0.1 \), \( c = 1 \), \( \tilde{\sigma}_c = 1 \), and three choices of the counterion valence: \( q = 2, 3, 4 \). As we see from the figure, in the SC regime a bound state always forms at zero external osmotic pressure. Second, the bound-state separation is smaller for larger counterion valences. Third, at zero osmotic pressure the equilibrium bound-state separation of thermally fluctuating membranes is consistently enhanced relative to the corresponding separation of the hard plates for the same counterion valences. Finally, at large values of \( \tilde{\ell} \) the pressure curves tend to a saturation value of \( \tilde{\rho} = -q/2 \) for counterion valence \( q \), identical to the case with no thermal fluctuations. Our prediction is thus that for multivalent counterion-mediated interactions, the equilibrium intermembrane spacing for soft and rigid surfaces, everything else being the same, should differ and the larger the valency the more they should differ. The predicted difference in equilibrium spacing can be in excess of a factor of 2, see Fig. 3.

2. Attractive square-well potential

Following Ref. [31], we describe the binding potential by an attractive square-well potential and study the effect that this square-well potential has on the fluctuation and free-energy behavior of a membrane using the variational framework we developed in Sec. III. As before we represent our system by a hard wall at \( z = 0 \) and a membrane whose surface is at a separation \( z = \hat{\ell}(x,\lambda) \). The square-well potential \( V(z) \) is defined by \( V(z) = V_0 \) for \( 0 < z < b \) and \( V(z) = 0 \) for \( z > b \). For an attractive potential \( V_0 < 0 \).

We represent the square-well potential in terms of Heaviside functions \( \Theta \), i.e.,

\[
\tilde{\wp} = \tilde{\wp}(|\ell(\lambda,\lambda)|) = \tilde{\ell}_0[\Theta(\tilde{\ell}(\lambda,\lambda)) - \Theta(\tilde{\ell}(\lambda,\lambda) - b)].
\]

The Gaussian approximation \( \tilde{\wp}_{\alpha} \) is given by Eq. (3.12):

\[
\tilde{\wp}_{\alpha} = \int_{-\infty}^{\infty} d\ell \frac{d}{\sqrt{2\pi}\sigma^2} \tilde{\ell}_0[\Theta(\tilde{\ell} - \tilde{\ell}_0) - \Theta(\tilde{\ell} - \tilde{\ell}_0 - b)] e^{-\ell^2/(2\sigma^2)}
\]

The variational free energy [cf. Eq. (3.19)] is given by

\[
f_{\text{var}} = \tilde{\ell}_0\left[\text{erf}\left(\frac{\tilde{\ell}_0}{\sqrt{2\sigma}}\right) - \text{erf}\left(\frac{\tilde{\ell}_0 - b}{\sqrt{2\sigma}}\right)\right] + \frac{(k_B T)^2}{2(k_B T^2)} + \frac{9k_B T c^2 \sigma^2}{8\tilde{\ell}_0^2} + \frac{3k_B T^2 c^2}{8\tilde{\ell}_0^2} + P\tilde{\ell}_0.
\]

We define a dimensionless separation distance \( \tilde{\ell}_0 \equiv \ell_0/b \), dimensionless mean-square fluctuation \( \tilde{\sigma} \equiv \sigma/b \), dimensionless well depth \( \tilde{V}_0 \equiv V_0 b^2 / 2\pi k_B T \), dimensionless temperature \( t \equiv k_B T / \kappa \), and dimensionless external osmotic pressure \( \tilde{\rho} \equiv P b^3 / k_B T \). In terms of these quantities, the dimensionless free energy is given by

\[
\tilde{f}_{\text{var}} = \frac{2}{2\sqrt{2\pi}} \left[\text{erf}\left(\frac{\tilde{\ell}_0}{\sqrt{2\sigma}}\right) - \text{erf}\left(\frac{\tilde{\ell}_0 - b}{\sqrt{2\sigma}}\right)\right] + \frac{t}{128\tilde{\sigma}_0^2} + \frac{9c^2 \sigma^2}{8\tilde{\ell}_0^2} + \frac{3c^2}{8\tilde{\ell}_0^2} + P\tilde{\ell}_0.
\]
is the well width) versus dimensionless separation which the membranes are maintained at a given separation, the same values of \( v \) for \( t = 0.1 \) and \( c = 1 \), and the following four binding strengths: (i) \( \tilde{v}_0 = 0 \) (black), (ii) \( \tilde{v}_0 = -0.04 \) (blue dashed), (iii) \( \tilde{v}_0 = -0.06 \) (red dotted), and (iv) \( \tilde{v}_0 = -0.08 \) (green dot-dashed). Inset: Behavior of dimensionless rms fluctuation \( \tilde{\sigma} \equiv \sigma/b \) (where \( b \) is the well width) versus dimensionless separation \( \tilde{t}^* \equiv \ell^*/b \) for the same values of \( t, c \), and the above four binding strengths.

to \( \ell_0 \) via

\[
\frac{V_0}{\sqrt{2\pi} \sigma^2} \left[ \left( \ell_0 - b \right) e^{-\left(\ell_0 - b\right)^2/(2\sigma^2)} - \ell_0 e^{-\ell_0^2/(2\sigma^2)} \right]
- \frac{(k_B T)^2}{64\kappa \sigma^3} + \frac{9k_B T c^2 \sigma}{4\ell_0^4} = 0. \tag{3.37}
\]

In dimensionless form, the above equation becomes

\[
\tilde{v}_0 \left[ \ell_0 e^{-\ell_0^2/(2\sigma^2)} - \left( \ell_0 - 1 \right) e^{-\left(\ell_0 - 1\right)^2/(2\sigma^2)} \right] + \frac{t}{64\sigma^4} - \frac{9c^2 \sigma^3}{4\ell_0^4} = 0. \tag{3.38}
\]

The behavior of the effective interaction energy between the membranes as a function of \( \ell_0 \) can be determined from Eq. (3.36) subject to the contraint on \( \tilde{\sigma} \) imposed by Eq. (3.38). To determine the external osmotic pressure at which the membranes are maintained at a given separation, we differentiate Eq. (3.36) with respect to \( \ell_0 \) and set it to zero (which is equivalent to making the saddle-point approximation \( \ell_0(0) \approx \ell_0^* \)). This yields

\[
\tilde{p} = \frac{3}{4(t^*)^3} + \frac{9g^2}{(t^*)^5} - \frac{\tilde{v}_0}{\sigma} \left[ e^{-\ell_0^2/(2\sigma^2)} - e^{-\tilde{\sigma}^2/(2\sigma^2)} \right]. \tag{3.39}
\]

For \( t = 0.1 \) and \( c = 1 \) the behavior of the rescaled osmotic pressure \( \tilde{p} \) versus the separation \( \tilde{t}^* \) and the behavior of the rescaled fluctuation amplitude \( \tilde{\sigma} \) as a function of \( \tilde{t}^* \) are plotted in Fig. 4. Note that the fluctuation amplitude is suppressed (relative to that of a purely steric system) for \( \ell_0^* < b \), whereas it is enhanced for \( \ell_0^* > b \). This is because for \( \ell_0^* < b \), the membrane effectively “sees” two repulsive (albeit one of which is finite) potential barriers and the repulsion has the effect of suppressing the amplitude of fluctuation, whereas for \( \ell_0^* > b \), the membrane effectively “sees” an attractive potential well which lessens the steric repulsion of the hard wall, and the fluctuation amplitude of the membrane is thus enhanced. For even larger values of \( \ell_0^* \), the fluctuation amplitude tends towards that of a purely steric membrane (represented by the black line), as it should.

We note that the use of the Gaussian variational approximation is reliable for sufficiently small well depths and/or membrane separations, a criterion of reliability being that the rms fluctuation behavior has to approach that of a purely steric membrane at sufficiently large membrane separations, as the square-well potential is short ranged. For larger well depths and/or larger separations, the application of the smooth Gaussian approximation to a sharp square well results in a certain oscillatory behavior reminiscent of the Gibbs phenomenon (which can be observed in the rms fluctuation behavior at large membrane separations) and the predictions specifically for the order of the unbinding transition are not reliable. In fact, the VGA-based formalism with attractive square-well potential and our steric potential predicts a discontinuous unbinding transition. This discrepancy with FRG-based approaches [20,21] that predict a continuous unbinding transition could arise from the relative smallness of the codimension (which is unity) of the membrane [41] and/or from the fact that the hard steric potential is being approximated by the soft(er)-, long(er)-range interaction of a finite \( \lambda \), reflecting the size of a soft boundary region that depends on the microscopic details of the chemical makeup of the membrane [12].

3. Morse potential

Let us now consider the following Morse potential, which has been used to describe the condensation of DNA molecules in multivalent salts [57,58] and to model the interactions of fluid membranes [7]:

\[
\tilde{w}(\ell) = w_1(\ell) + w_2(\ell), \tag{3.40a}
\]

\[
w_1(\ell(\chi_0)) = R e^{-\chi_0/(\chi_1)}, \tag{3.40b}
\]

\[
w_2(\ell(\chi_0)) = -A e^{-\chi_0/(\chi_1)}. \tag{3.40c}
\]

The Morse potential has three fitting parameters: the strength of (short-range) repulsion \( R \), strength of (longer-range) attraction \( A \), and an inverse length scale \( \kappa p \). Applying the variational approximation to \( w_{\tilde{\sigma}} \) [with the aid of Eqs. (3.12) and (3.40)], we obtain

\[
\tilde{w}_{\tilde{\sigma}} = \int_{-\infty}^{\infty} \frac{d\ell}{\sqrt{2\pi} \sigma^2} \left( R e^{-\kappa p \ell} - A e^{-\kappa p \ell} \right) e^{-\tilde{\sigma}^2/(2\sigma^2)} = R e^{-\kappa p \ell_0} e^{\tilde{\sigma}^2/(2\sigma^2)} - A e^{-\kappa p \ell_0} e^{\tilde{\sigma}^2/(2\sigma^2)}. \tag{3.41}
\]

The variational free energy per unit area [defined in Eq. (3.19)] becomes

\[
f_{\text{var}} = R e^{-\kappa p \ell_0} e^{\tilde{\sigma}^2/(2\sigma^2)} - A e^{-\kappa p \ell_0} e^{\tilde{\sigma}^2/(2\sigma^2)} + \frac{(k_B T)^2}{128\kappa \sigma^2} + \frac{3k_B T c^2}{8\ell_0^4} + \frac{3k_B T c^2}{8\ell_0^4} + P \ell_0. \tag{3.42}
\]

Defining dimensionless quantities \( u_1 \equiv \beta k_B c^2 R, u_2 \equiv \beta k_B c^2 A, f \equiv \beta k_B c^2 f_{\text{var}}, \ell_0 \equiv \kappa p \ell_0, \tilde{\sigma} \equiv \kappa p \sigma, \tilde{p} \equiv \beta k_B c^2 P, \) and \( t \equiv k_B T/k \), we can recast the above free energy in dimensionless
form:
\[ \tilde{f} = \frac{u_1 e^{-\tilde{\ell}_0 + \frac{1}{2} \tilde{\sigma}^2}}{8 \tilde{\ell}_0} - \frac{u_2 e^{-\tilde{\ell}_0 + \frac{1}{2} \tilde{\sigma}^2}}{8 \tilde{\ell}_0} + \frac{3c_2^2}{8 \tilde{\ell}_0} + \frac{t}{128 \tilde{\sigma}^2} + \frac{9c_2^2 \tilde{\sigma}^2}{8 \tilde{\ell}_0} + \tilde{p} \tilde{\ell}_0. \]  

(3.43)

By varying \( \tilde{f} \) with respect to \( \tilde{\sigma} \), we obtain a self-consistent relation:
\[ \frac{u_1}{2} e^{-\tilde{\ell}_0 + \frac{1}{2} \tilde{\sigma}^2} - \frac{u_2}{8} e^{-\tilde{\ell}_0 + \frac{1}{2} \tilde{\sigma}^2} - \frac{t}{128 \tilde{\sigma}^2} + \frac{9c_2^2}{8 \tilde{\ell}_0} - \tilde{\ell}_0 = 0. \]  

(3.44)

In the saddle-point approximation, the equilibrium separation \( \langle \tilde{\ell}_0 \rangle \) is given by the solution \( \tilde{\ell}_0 = \tilde{\ell}_c \) to \( \partial \tilde{f} / \partial \tilde{\ell}_0 = 0 \):
\[ \tilde{p} = u_1 e^{-\tilde{\ell}_0 + \frac{1}{2} \tilde{\sigma}^2} - \frac{u_2}{2} e^{-\tilde{\ell}_0 + \frac{1}{2} \tilde{\sigma}^2} + \frac{9c_2^2 \tilde{\sigma}^2}{2 \tilde{\ell}_0^3} + \frac{3c_2^2}{4 \tilde{\ell}_0^3}. \]  

(3.45)

In Fig. 5 the behavior of \( \tilde{f} \) as a function of \( \tilde{p} \) and the behavior of \( \tilde{\sigma} \) as a function of \( \tilde{\ell}_c \) are plotted for \( c = 1, \kappa = 10k_B T \), \( \tilde{\ell}_c \ll \sqrt{\delta} \), and the following four cases: (i) \( u_1 = u_2 = 0 \) (black), (ii) \( u_1 = 1, u_2 = 0.5 \) (blue, dashed), (iii) \( u_1 = u_2 = 1 \) (red, dotted), and (iv) \( u_1 = 1, u_2 = 2 \) (green, dot-dashed). Note that for cases (ii) and (iii), the rms fluctuation of the membrane is smaller than the steric-only case (i) for \( \tilde{\ell}_c \ll 1 \), as the repulsive interaction dominates in this range of separations. At separations larger than \( \tilde{\ell}_c \sim 1 \), the attractive \( u_2 \) interaction dominates over the repulsive \( u_1 \) interaction, and the rms fluctuation is enhanced relative to the steric-only case, becoming larger for larger interaction strengths \( u_2 \). At still larger separations the rms fluctuation of all four cases converge as the steric potential [which decays as \( (\tilde{\ell}^c)^{-2} \)] dominates over the exponentially decaying attractive tail. The rms fluctuation goes to zero at \( \tilde{\ell}^c = 0 \) due to the hard-wall constraint. For \( u_2 > 0 \) the membranes are always bound at zero external osmotic pressure, and the bound-state separation is smaller for larger values of \( u_2 \).

4. Hydration and van der Waals forces

Let us now consider the case of two uncharged membranes interacting via hydration and van der Waals forces, a generic case of interacting zwitterionic lipid membranes [40,43]. For a pair of membranes of finite thickness \( \delta \), the interaction potential can be expressed as [17,40]
\[ \tilde{w}(\tilde{\ell}) = A_H e^{-\tilde{\rho}} - \frac{W}{12\pi} \left[ \frac{1}{\tilde{\ell}^2} - \frac{2}{(\tilde{\ell} + \delta)^2} + \frac{1}{(\tilde{\ell} + 2\delta)^2} \right], \]  

(3.46)

where the first term describes repulsion due to hydration forces and the second term describes van der Waals attraction of Hamaker strength \( W \). For small membrane undulations, we can expand \( \tilde{w}(\tilde{x}_0) \) around \( \tilde{\ell}_0 \) to quadratic order in \( \delta(\tilde{x}_0) \). Using Eqs. (3.12) and (3.19), we obtain
\[ \beta f_{\text{sw}} = \frac{k_B T}{128 \kappa \sigma^2} + \frac{3c^2}{8 \tilde{\ell}_0} + \beta A_H e^{-\tilde{\rho}} + \beta P \tilde{\ell}_0 \]
\[ + \left[ \frac{9c^2}{8 \tilde{\ell}_0} - \frac{\beta W}{4\pi} \left( \frac{1}{\tilde{\ell}_0^2} - \frac{2}{(\tilde{\ell}_0 + \delta)^2} + \frac{1}{(\til{\ell}_0 + 2\delta)^2} \right) \right] \sigma^2 \]
\[ - \frac{\beta W}{12\pi} \left[ \frac{1}{\til{\ell}_0^2} - \frac{2}{(\til{\ell}_0 + \delta)^2} + \frac{1}{(\til{\ell}_0 + 2\delta)^2} \right]. \]

(3.47)

Defining rescaled quantities \( t = k_B T / \kappa, \tilde{\ell}_0 \equiv \tilde{\ell}_0 / \lambda_H, \tilde{\sigma} \equiv \delta / \lambda_H, A_H \equiv \beta A_H \lambda_H^2, \tilde{\rho} \equiv \beta P \tilde{\ell}^2, \tilde{w} \equiv \beta W / 12\pi \) and \( \tilde{f} \equiv \beta \lambda_H^2 f_{\text{sw}} \), we can re-express the above equation in dimensionless form:
\[ \tilde{f} = \frac{t}{128 \til{\ell}_0^2} + \frac{3c^2}{8 \til{\ell}_0} + \tilde{A}_H e^{-\til{\rho}} + \tilde{p} \tilde{\ell}_0 \]
\[ + \left[ \frac{9c^2}{8 \til{\ell}_0} - \frac{3\til{w}}{\til{\ell}_0^2} - \frac{2}{(\til{\ell}_0 + \delta)^2} + \frac{1}{(\til{\ell}_0 + 2\delta)^2} \right] \til{\sigma}^2 \]
\[ - \frac{\til{w}}{\til{\ell}_0} \left[ \frac{1}{\til{\ell}_0^2} - \frac{2}{(\til{\ell}_0 + \delta)^2} + \frac{1}{(\til{\ell}_0 + 2\delta)^2} \right]. \]

(3.48)

The relation between \( \sigma^2 \) and \( \til{\ell}_0 \) is given by Eq. (3.20), which yields
\[ \tilde{A}_H e^{-\til{\rho}} = \frac{t}{64\pi \til{\ell}_0^2} + \frac{9c^2}{4 \til{\ell}_0^3} \]
\[ - 6\til{w} \left[ \frac{1}{\til{\ell}_0^2} - \frac{2}{(\til{\ell}_0 + \delta)^2} + \frac{1}{(\til{\ell}_0 + 2\delta)^2} \right] = 0. \]

(3.49)

In Fig. 6, we study the behavior of the free energy and external osmotic pressure as functions of intermembrane separation for fixed hydration strength \( A_H = 0.2 \) J m\(^{-2}\), hydration length scale \( \lambda_H = 0.3 \) nm, and bilayer thickness \( \delta = 4 \) nm. The critical point \( \tilde{\ell}_c = \tilde{\ell}_c^* \) and \( \tilde{\sigma}^* \) is determined numerically; we find that \( \tilde{\ell}_c = 0.049902 \) and \( \tilde{\sigma}^* = 0.2548 \). We also find the critical separation \( \tilde{\ell}_c = 0.2694 \) and the critical rms fluctuation amplitude \( \alpha = 4.76 \delta \). For Hamaker strengths greater than \( \tilde{\ell}_c \), the system exhibits phase coexistence similar to the one found in the case of the attractive square well (Sec. III A 2). The threshold Hamaker strength at which the membranes undergo a discontinuous and complete unbinding transition at zero external osmotic pressure is estimated to be \( \tilde{w}_d = 0.061 \) (the blue disks in Fig. 6).
Effective Interactions Between Fluid Membranes

On the other hand, the zero-mode-dependent part of the steric potential always scales as $\ell_0^{-2}$. Concomitantly, we also derived a closed-form formula [see Eq. (2.23)] for the rms undulation amplitude $\sigma$, viz.,

$$\sigma^2 = \frac{\ell_0^2}{12c} \sqrt{\frac{k_B T}{\kappa}} \left[ 1 - \frac{2}{\pi} \tan^{-1} \left( \frac{2\ell_0^2}{3cS \sqrt{k_B T}} \right) \right] \text{, (4.2)}$$

which has the following asymptotic behavior: for $\ell_0 \ll \sqrt{S}$, $\sigma$ scales linearly with $\ell_0$, whereas for $\ell_0 \gg \sqrt{S}$, $\sigma$ saturates at the order of $k_B T \sqrt{S/\kappa}$. The rms fluctuation amplitude becomes small at low temperatures $T$ and/or large bending stiffnesses $\kappa$. We believe that our result refines and substantiates the ansatz $\sigma^2 = \mu \ell_0^2$ first postulated (on the basis of heuristic arguments) in Ref. [2].

To investigate fluid membrane systems that experience interactions of non-Gaussian form, we have adapted the Feynman-Kleinert version of the variational Gaussian approximation (VGA) to the case of fluid membranes subject to our effective steric potential $V_s$. We have applied this VGA approach to different types of potential: (i) the Moreira-Netz potential for a pair of strongly charged membranes with an intervening solution of multivalent counterions, (ii) an attractive square well, (iii) the Morse potential, and (iv) a combination of hydration and van der Waals interactions.

In the first case we make a prediction that, everything else being the same, the multivalent counterion-mediated interaction measured between hard and soft surfaces should display a substantial difference in the equilibrium spacing, with soft surfaces displaying larger equilibrium spacing. This difference should increase with the valency of the counterions and could easily reach a factor of 2 for high valency counterions and should thus be eminently measurable in the planned osmotic-stress experiments with lipid membranes in the presence of multivalent salts [59]. We furthermore note here that our results for multivalent salts imply also a pronounced effect on the estimated values of the bending rigidities that could be extracted from the linewidth of the x-ray scattering intensity in these types of experiments, irrespective of whether they directly renormalize the bending rigidity of lipid membranes or not [60–62].

Within the same VGA approach we also analyzed in detail the three other cases of the coupling between long-range interactions and conformational fluctuations, showing the versatility and usefulness of our approach in the context of widely differing types of long-range interactions in the regime of intermediate separations, which are also the typical length scales of biologically relevant systems.

As future projects in the same general direction, our self-consistent theory can be employed to study multicomponent membranes, membranes with nonzero surface tension, and tethered and polymerized membranes.

ACKNOWLEDGMENT

The authors thank A. C. Maggs, G. Pabst, D. J. G. Crow, P. Zitherl, A. Siber, B. Kollmitzer, and S. Gupta for rewarding discussions and acknowledge the financial support of the Agency for research and development of Slovenia (ARRS) under the bilateral SLO-A Grant No. N1-0019.

Besides heuristic arguments for the \( c_\text{H}(k_B T)^2/k_B T \) form of the steric potential, arguments have also been proposed based on the more mathematically rigorous functional renormalization group approach [13]. By locating the family of asymptotic solutions to the fixed-point equation satisfying a hard-wall boundary condition at \( d = 0 \) and another boundary condition at \( d \to \infty \), one can obtain the correct \( d^{-2} \) scaling behavior of the steric potential, but the solution leaves indeterminate the prefactor of the potential. An infinite variety of superpositions of \( (k_B T)^2/k_B T \) \( n \) arbitrary) are possible, and by choosing the \( n = 1/2 \) contribution the author of Ref. [13] identifies the steric potential to be the same as the Helfrich potential. However, other choices are possible. For example, the choice \( d \sim \sqrt{k_B T/k_B T + c} \) is also a solution to the leading-order near-field asymptotics of the fixed-point renormalization group equation Eq. (9) of Ref. [13], and this is equivalent to the steric potential in the first term of the right-hand side of Eq. (2.31).

The analogy may be used to obtain rough estimates for our free parameter \( c \). Equating the Helfrich potential \( V_H \) and the first term of Eq. (2.31) yields a relation between \( c_B \) and \( c \): \( c_B = (3c/16)\sqrt{\kappa/k_BT} \). The stiffness of egg lecithin at room temperature \( (T = 298 \text{ K}) \) can take a range of values, viz., \( 0.5 \times 10^{-19} \text{ J} \leq \kappa \leq 2.3 \times 10^{-19} \text{ J} \) (see, e.g., Refs. [4,40]). Taking the upper measured value \( \kappa \approx 2.3 \times 10^{-19} \text{ J} \) and using an estimate \( c_B \approx 1 \) [3], we obtain \( c \approx 0.7 \). On the other hand, if we use the Monte Carlo results of Ref. [31] or those of W. Janke, H. Kleinert, and M. Meinhart [Phys. Lett. B 217, 525 (1989)], which indicate that \( c_B \approx 0.1 \), then we obtain \( c \approx 0.07 \). Conversely, if we take the lower measured value \( \kappa \approx 0.5 \times 10^{-19} \text{ J} \) and \( c_B \approx 1 \) [3], we obtain \( c \approx 1.53 \). Using \( c_B \approx 0.1 \) would yield \( c \approx 0.153 \). For the main part of our paper we have assumed for simplicity that \( c = 1 \).

G. Pabst (personal communication).
